NORMAL AGE-RELATED VARIATIONS: INFANT/CHILD

Common musculoskeletal variations in newborns and children include:

- C-shaped curve of spine at birth; the anterior cervical curve develops at about ages 3 to 4 months, and the anterior lumbar curve develops between ages 12 and 18 months
- Lordosis (an exaggerated lumbar curve)
- Pronation of the feet in children between ages 12 and 30 months
- Genu varum (bowleg) for 1 year after learning to walk

NORMAL AGE-RELATED VARIATIONS: OLDER ADULT

Common musculoskeletal variations seen in older adults include:

- Loss of muscle mass and strength
- Decreased ROM
- Kyphosis
- Decreased height
- Osteoarthritic changes in joints

Assessing the Neurologic System

Neurologic assessment includes cerebral function, cranial nerve function, cerebellar function, motor and sensory function, and reflexes. The health history is useful in obtaining information about ADLs and other pertinent data, such as dizziness, loss of sensation, headaches, and ability to see, hear, taste, and detect sensations. Physical examination is conducted to identify mental status and level of consciousness, cranial nerve function, muscle strength and coordination, and reflexes. Normally, the patient is alert and responsive, has full sensory function, and all muscle groups are bilaterally strong. Abnormal findings are discussed with specific parts of the examination that follow. Many health care providers assess the neuromuscular, musculoskeletal, and peripheral vascular systems as an integrated assessment. Refer to Skill 27-2 (on pp. 824–830) for an example of a systematic, integrated assessment of these systems.

HEALTH HISTORY

Identify risk factors for altered health during the health history by asking about the following:

- History of numbness, tingling, or tremors
- History of seizures
- History of headaches or dizziness
- History of trauma to the head or spine
- History of high blood pressure or stroke
- Changes in the ability to hear, see, taste, or smell
- Loss of ability to control bladder and bowel
- History of smoking (how long, how many packs/day)
- History of chronic alcohol use
- History of diabetes mellitus or cardiovascular disease
- Use of prescription and over-the-counter medications

PHYSICAL ASSESSMENT

Evaluate cerebral function by observing the patient's behavior throughout the health history interview and physical assessment. Assess the patient's mental status, memory, emotional status, cognitive abilities, and behavior. Evaluate cerebellar function by assessing motor skills, coordination, and balance. Assess the sensory system by having the patient

identify various sensory stimuli, and evaluate the reflexes by contraction of specific muscles.

Equipment for a neurologic assessment includes a visual acuity chart, a penlight, a sharp object (e.g., a large safety pin), cotton balls, a tongue depressor, and familiar objects, such as a key or coin. The patient should be sitting, if possible, and the environment should be quiet. Advanced practice professionals typically perform assessment of deep tendon reflexes to determine the functional ability of specific spinal segment levels. Refer to a health assessment text for details.

Assessing Mental Status

Mental status assessment includes level of consciousness, level of awareness, behavior and appearance, memory, and language. On initial contact, assess the patient's level of consciousness and begin to evaluate the patient's orientation to person, place, and time, as well as cognitive abilities and affect (whether the patient knows who they are, where they are, and the day or month or year). Observe the patient's appearance, general behavior, ability to speak clearly, and their ability to respond to questions.

Assess the patient's overall appearance. The patient should have a clean, neat appearance with erect posture; should be oriented to person, place, and time; should have memory recall (both short- and long-term memory); and should be able to demonstrate coherent and logical thought processes. Abnormal findings include poor hygiene, inappropriate dress, disorientation, absent memory recall, and incoherent or illogic thought processes. These abnormal findings may indicate a mental health disorder, developmental delay, brain disease, cerebrovascular disorder, alcohol or drug intoxication, or a tumor.

Think back to **Tammy Browning**, the pregnant woman with a history of substance abuse. The nurse would assess the patient's mental status for clues suggesting recent drug use, incorporating knowledge of abnormal findings into the assessment.

The following discussion of each of the mental status components includes sample questions or specific assessments to use during the assessment.

Assessing Level of Consciousness. Consciousness is the degree of wakefulness or the ability of a person to be aroused. This is not the same as orientation; a patient may be conscious but not oriented. Level of consciousness is described as follows:

- Awake and alert: fully awake; oriented to person, place, and time; responds to all stimuli, including verbal commands
- Lethargic: appears drowsy or asleep most of the time but makes spontaneous movements; can be aroused by gentle shaking and saying patient's name
- Stuporous: unconscious most of the time; has no spontaneous movement; must be shaken or shouted at to arouse; can make verbal responses, but these are less likely to be appropriate; responds to painful stimuli with purposeful movements
- Comatose: cannot be aroused, even with use of painful stimuli; may have some reflex activity (such as gag reflex); if no reflexes present, is in a deep coma

The Glasgow Coma Scale (GCS) (Table 27-4) is a standardized assessment tool that assesses level of consciousness. The GCS is used as a rapid evaluation of the status of acutely ill patients at risk of acute brain damage (Derbyshire & Hill, 2018). Some limitations to using the GCS include the inability to assess the verbal score after the patient has been intubated; a lack of assessment of respiration and brainstem reflexes; inability to assess a possible developing vegetative state; and inability to recognize pseudocoma.

The FOUR (Full Outline of UnResponsiveness) score coma scale (Table 27-5) is an assessment tool for adult and pediatric patients with severe neurologic impairment (Hickey, 2020). It includes information not assessed by the GCS, including measurement of brainstem reflexes; determination of eye opening, blinking, and tracking; a broad spectrum of motor responses; and the presence of abnormal breath rhythms and a respiratory drive, providing a more comprehensive neurologic assessment (Jalali & Rezaei, 2014; Zappa et al., 2020). The FOUR score tool does not include an assessment of verbal response and may be more useful for assessing critically ill patients with depressed level of consciousness (Almojuela et al., 2019). Because the FOUR score, unlike the GCS, does not include an assessment of verbal response, it is more useful for assessing critically ill patients who have undergone intubation (Iyer et al., 2009; Sadaka et al., 2012).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Table 27-4 Glasgow Coma Scale

The Glasgow Coma Scale (GCS) is a tool used to assess arousal and level of consciousness and coma (Morton & Fontaine, 2018). The GCS evaluates three key categories of behavior that most closely reflect activity in the higher centers of the brain: eye opening, verbalization, and movement (Morton & Fontaine, 2018; Waterhouse, 2005). Within each category each level of response is given a numerical value. The maximal score is 15 indicating a fully awake, alert, and oriented patient; an overall score of 8 or below is associated with coma (Hickey, 2020; Morton & Fontaine, 2018).

COMPONENT	SCORE	RESPONSE
Eye opening	4	Spontaneous eye opening
	3	Eyes open to speech
	2	Eyes open to pain
	1	No eye opening
Motor response	6	Obeys commands fully
	5	Localizes to noxious stimuli
	4	Withdraws from noxious stimuli
	3	Abnormal flexion (i.e., decorticate posturing; flexes elbows and wrists while extending lower legs to pain)
	2	Abnormal extensor response (i.e., decerebrate posturing; extends upper and lower extremities to pain)
	1	No motor response
Verbal response	5	Alert and oriented
	4	Confused yet coherent speech
	3	Inappropriate words and jumbled phrases consisting of words
	2	Incomprehensible sounds
	1	No verbal response

Source: Adapted from Hickey, J. V. (2020). *The clinical practice of neurological and neurosurgical nursing* (8th ed.). Wolters Kluwer; reprinted from *The Lancet*, Teasdale, G., & Jennett, B. Assessment of coma and impaired consciousness. A practical scale. *Lancet, 2*(7872), 81–84, Copyright 1974, with permission from Elsevier.

Table 27-5 Full Outline of Un-Responsiveness (FOUR) Coma Scale

The FOUR coma scale combines the most important neurologic signs into an easy-to-use scale with four components. The maximum score in each of these components is 4. The components are not totaled or summed and can be used to detect decreasing consciousness, increasing intracranial pressure, and brain herniation, as well as predict patient outcome (Iyer et al., 2009; Mercy et al., 2013; Oh et al., 2019; Sadaka et al., 2012; Wijdicks et al., 2005; Zappa et al., 2020).

	0	1	2	3	4
Eye response	E0: Eyelids remain closed with pain	E1: Eyelids closed but open to pain	E2: Eyelids closed but open to loud voices	E3: Eyelids open but not tracking	E4: Eyelids open or opened, tracking or blinking to command
Motor response					
Note: Ask patients to make a peace sign, a fist, and show thumbs up	M0: No response to pain	M1: Extension response to pain	M2: Flexion response to pain	M3: Localizing to pain	M4: Thumbs up, fist, or peace sign
Brainstem reflexes	B0: Absent pupil, corneal, and cough reflex	B1: Pupil and corneal reflexes absent	B2: Pupil or corneal reflexes absent	B3: One pupil wide and fixed	B4: Pupil and corneal reflexes present
Respiration	R0: Breathes at ventilator rate or apnea	R1: Breathes above ventilatory rate	R2: Not intubated, irregular breathing	R3: Not intubated, Cheyne–Stokes breathing pattern	R4: Not intubated, regular breathing pattern

Source: Reprinted from Elsevier, Iyer, V. N., Mandrekar, J. N., Danielson, R. D., Zubkov, A. Y., Elmer, J. L., & Wijdicks, E. F. (2009). (2012). The FOUR score predicts outcome in patients after traumatic brain injury. *Neurocritical Care*, *16*(1), 95–101.

Assessing Level of Awareness. Assess awareness by evaluating orientation to time, place, and person. The following questions may be used:

- *Time:* What is today's date? What day of the week is it? What season of the year is this? What was the last holiday?
- *Place:* Where are you now? What is the name of this city? What state are we in?
- *Person:* What is your name? How old are you? Who came to visit you this morning?

Although exceptions may occur, people who have impaired awareness first lose time orientation, followed by place orientation, and then person orientation. Remember that it is often difficult to know the exact date when one is ill, in

pain, or in unfamiliar surroundings.

Assessing Memory. Assess memory by asking questions that require answers demonstrating immediate recall and recall for past events. To assess immediate memory, ask the patient to repeat a series of numbers forward or backward (e.g., 3, 6, 9). Start with three numbers and gradually increase the digits until the patient cannot respond correctly. Most adults can repeat a series of five to eight numbers forward and four to six digits backward. You might also ask, "What did you eat for breakfast this morning?" To assess past memory, ask, "When is your birthday?" or "When is your wedding anniversary?"

Assessing Language

The cerebral cortex controls the ability to express self through writing, words, or gestures and to understand the spoken and written word. Some simple methods of assessing language capabilities include asking the patient to name items in the room (e.g., bed, flowers, gown, pajamas), to follow simple commands (such as "Point to your head"), to read a short sentence aloud, or to match printed and spoken words with appropriate pictures. Injury to the cortex can cause aphasia, which is a disorder of language ability. Aphasia may be expressive (the person understands written and spoken words but cannot write or speak to communicate effectively) or receptive (the person cannot understand written or spoken words). These aphasias may also be combined.

Assessing Cranial Nerve Function

The function of the 12 cranial nerves is assessed primarily during the neurologic assessment, although parts of cranial nerve function are assessed with other body systems (e.g., capillary response during assessment of the face). Each nerve has a specific function and is evaluated individually. Table 27-6 outlines the cranial nerves, with their function and assessment methods.

Assessing Motor and Sensory Function

Motor ability is evaluated by assessing balance, gait, and coordination. Sensory function is assessed by testing sensory discrimination of pain, light touch, and vibrations.

Inspecting Balance and Gait. Evaluate balance and gait by having the patient walk across the room on the toes, on the heels, and heel to toe. Observe posture, balance, and arm and leg movements. The posture should be erect, with slight swaying in the standing position. Walking (gait) should be smooth and rhythmic, with arms swinging at the sides.

Assessing Motor Function and Coordination. Evaluate motor function and coordination by having the patient rapidly touch each finger with the thumb, rapidly pat the hand on the thigh, and tap the foot on the floor (or against your hand, if the patient is supine). Repeat the sequence on the opposite limb. Normally, the movements are coordinated. If the patient is unable to perform these movements, it may indicate disease of the upper motor neurons or cerebellum.

Assessing Sensory Perception. Test sensory perception by evaluating the patient's response to pain, light touch, and normal shapes. With the patient's eyes closed, randomly touch the skin on the upper and lower extremities and the trunk with a sharp object and a soft object. The assessment proceeds from distal (hands, arms, feet, or legs) to proximal (the trunk). The patient should be able to distinguish between sharp (painful) and soft or dull touch. Sensory perception may also be assessed by asking the patient to close the eyes and identify familiar objects (such as a coin or key) by touching them. Abnormal findings include inability to perceive pain or light touch, inability to identify the location of touch, and inability to identify familiar objects.

Neurovascular Assessment. Assessment of neurovascular status is an important nursing intervention leading to early identification of neurovascular impairment and timely intervention (Agency for Clinical Innovation, 2018; Johnston-Walker & Hardcastle, 2011; Turney et al., 2013). Refer to the discussion of neurovascular assessment earlier in the chapter. See Box 27-8 (on page 805) for an outline of the components of a neurovascular assessment.

Table 27-6 Summary of Cranial Nerves

NERVE (NUMBER)	TYPE	FUNCTIONS	METHODS FOR EXAMINING NERVE
Olfactory (I)	Sensory	Sense of smell	Test each nostril for smell reception with various agents and interpretation
Optic (II)	Sensory	Sense of vision	Test vision for acuity and visual fields
Oculomotor (III)	Motor	Pupil constriction	

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	Raise eyelids	Test pupillary reaction to light and ability to open and close eyelids	
Trochlear (IV)	Motor/proprioceptor	Downward, inward eye movement	Test for downward and inward movement of the eye
Trigeminal (V)	Motor	Jaw movements—chewing and mastication	Ask patient to open and clench jaws while you palpate the jaw muscles
	Sensory	Sensation on the face and neck	Test face and neck for pain sensations, light touch, and temperature
Abducens (VI)	Motor	Lateral movement of the eyes	Test ocular movement in all directions
Facial (VII)	Motor	Muscles of the face	Ask the patient to raise eyebrows, smile, show teeth, and puff out cheeks
	Sensory	Sense of taste on the anterior two thirds of the tongue	Test for the taste sensation with various agents
Acoustic (VIII)	Sensory	Sense of hearing	Test hearing ability
Glossopharyngeal (IX)	Motor	Pharyngeal movement and swallowing	Ask the patient to say “ah,” and have patient yawn to observe upward movement of the soft palate; elicit gag response; note ability to swallow
	Sensory	Sense of taste on the posterior one third of the tongue	Test for taste with various agents
Vagus (X)	Motor/sensory	Swallowing and speaking	Ask the patient to swallow and speak; note hoarseness
Accessory (XI)	Motor/sensory	Movement of shoulder muscles	Ask the patient to shrug shoulders against your resistance
Hypoglossal (XII)	Motor	Movement of the tongue; strength of the tongue	Ask the patient to protrude tongue; ask patient to push tongue against cheek

NORMAL AGE-RELATED VARIATIONS: INFANT/CHILD

Common neurologic variations for newborns and children include:

- Positive Babinski sign (normal in children less than 24 months) (Jensen, 2019)
- Grasp reflex (present at birth)
- Motor control develops in head, neck, trunk, and extremities sequence

NORMAL AGE-RELATED VARIATIONS: OLDER ADULT

Common neurologic variations for older adults include:

- Slower thought processes and verbal responses
- Decreased sensory ability (hearing, sight, smell, taste, temperature, pain)
- Slower coordination and voluntary movements
- Decreased reflex responses

- Appearance of confusion in unfamiliar surroundings
- Slower gait, with a wider base and flexed hips and knees

DOCUMENTATION OF DATA

After completing the health history and physical assessment, organize all health assessment data to identify actual and potential health problems, identify diagnoses or patient problems, plan appropriate care, and evaluate the patient's responses to interventions. Document the data, with each system recorded individually. Box 27-10 (on page 820) illustrates an example of a health history and physical assessment documentation.

A pattern is often established that begins during the history and is confirmed during the physical assessment. For example, a health history of a woman diagnosed with multiple sclerosis (a neurologic disorder) might include data about fatigue and increased weakness and muscle spasms in the legs. Physical examination findings would include decreased muscle strength in the lower extremities. These data may be used to support the identification of a health problem of Activity Intolerance.

Box 27-10 Documenting a Health Assessment

Mrs. D. comes to a local community outpatient facility for intolerance of eating fatty foods. She says, "I just started having a lot of gas and was sick to my stomach after eating fried foods." The nurse makes the following assessments.

Notes:
Maternal grandmother died of diabetes complications at 69 years of age.
Paternal grandfather died of stroke at 82 years of age.
Paternal grandmother died of unknown causes at 55 years of age.
Sister, 49 years of age, healthy

Health History

Mrs. D. is a 52-year-old woman who lives with her 54-year-old husband on a farm in a rural midwestern area. She graduated from high school and is employed as a secretary for a local insurance facility. Mrs. D. is well groomed, alert, and oriented. She occasionally takes over-the-counter medications for constipation and colds. She takes a prescription medication twice a day for "high blood pressure." She says she has about two mixed drinks a week and does not smoke. She has had five pregnancies, resulting in five living children.

Mrs. D. had her tonsils removed at age 5 years, had an appendectomy at age 22 years, and is allergic to

penicillin (causes rash and difficulty breathing). She has had all her immunizations, but her last tetanus shot was 10 years ago. Her family history of illness is as follows:
Maternal grandfather died of heart problems at age 77 years.
Maternal grandmother died of diabetes complications at age 69 years.
Paternal grandfather died of stroke at age 82 years.
Paternal grandmother died of unknown causes at age 56 years.
Sister, age 49 years, healthy.
Brother died at age 22 years in a car accident.

Physical Assessment

Vital signs: T = 98.8°F (orally), P = 82 beats/min, R = 16 breaths/min, BP = 150/88 mm Hg
Height/weight: 5 ft, 4-inch tall, 178 lb
Integument: Skin warm and dry, normal turgor. Numerous freckles over face and arms. Old scar, RLQ (appendectomy). Nails convex and smooth. Hair dark brown, shiny, normal distribution.
Head and neck: Skull size and shape normal. Facial features symmetric. Can raise eyebrows, close eyes, smile, and puff out cheeks. External eye structures symmetric. Sclera white, conjunctiva pink. Wears glasses to correct near-sightedness. Vision with glasses 20/30-2 on Snellen chart. Pupils equal, round, and react to light bilaterally. Demonstrates accommodation, convergence, and peripheral vision. External ears symmetric. Canals smooth and pink without excess cerumen. Right nostril clear, left nostril occluded with mucus. Left maxillary sinus slightly tender on palpation. Teeth in good repair with six fillings. Oral mucous membranes pink. Tonsils absent. Trachea midline. No lymph nodes palpable.
Thorax/lungs/heart: Thorax symmetric with equal expansion. Respirations even and unlabored. Lung sounds clear. No visible pulsations noted in neck or precordium. S_1 and S_2 heard at pulmonic, aortic, tricuspid, and mitral areas. No extra heart sounds, or murmurs heard. Apical pulse 84 beats/min and regular.
Breasts and axilla: Skin pink. No dimpling or retraction noted. Areolae and nipples dark brown, no crusting or drainage. No masses palpated in breasts. Axillary lymph nodes are not palpable. To have mammogram at next visit.
Abdomen: Obese, rounded. Umbilicus midline. No pain on light palpation. Bowel sounds heard in all four quadrants. No bruits heard on auscultation.
Peripheral vascular: Pulses equal in both arms. Pulses equal in both legs. No edema present. Superficial varicose veins present on both lower extremities between ankle and knee. Toenails thick and yellow.
Genitalia: Will be assessed at next visit with pelvic and Papanicolaou smear.
Rectum and anus: Inspected only. Small external hemorrhoids noted.
Musculoskeletal: Stands erect. Normal spinal curves. No joint deformities, tenderness, or crepitation. Full active ROM in all joints. Muscle strength equal bilaterally, slightly stronger on the right (dominant side).
Neurologic: Alert and oriented to time, place, and person. Facial expressions appropriate. Speech clear and appropriate. Demonstrates long- and short-term memory. All cranial nerves tests were intact. Gait even.

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the goal of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop expertise in performing health assessments, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following while performing health assessment and providing nursing care:

- Did your preparation and practice related to performing health assessment result in your feeling confident in your ability to gather reliable, accurate data? Did your competence and confidence inspire the patient's, family's, and caregiver's trust?
- How did you prioritize the data you collected? What patterns in the data did you identify? What knowledge from your learning, personal experience, and intuition did you use to make decisions and develop your plan of care?
- How confident are you that the data you reported and recorded accurately communicates the health status, health problems, issues, risks, and strengths of the patient? How successfully have you communicated this information to other members of the health care team? How successfully have you communicated who this patient/family is to the interdisciplinary team?
- Were you aware of any cultural and/or ethnic beliefs or practices that may have influenced the health assessment? Were you aware of any stereotypes or prejudices that might have negatively influenced the clinical encounter? If so,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

how did you address these?

- Was the patient/family/caregiver participation in the process at an optimal level? How might you have better engaged the patient, family, and caregivers? As you concluded your assessment, did the patient/family/caregivers know your name, and know what to expect of you and your nursing care? Did the patient sense that you are respectful, caring, and competent to obtain accurate and relevant data?

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of assessing their health status? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Skill 27-1 Using a Portable Bed Scale

DELEGATION CONSIDERATIONS

Measurement of body weight may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Bed scale with sling
- Cover for sling
- Sheet or bath blanket
- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Check the prescribed interventions or plan of care for frequency of weight measurement. More frequent measurement of the patient's weight may be appropriate based on nursing judgment. Obtain the assistance of a second caregiver, based on the patient's mobility and ability to cooperate with the procedure.	This provides for patient safety and appropriate care.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures that the right patient receives the intervention and helps prevent errors.
4. Close the curtains around the bed and close the door to the room if possible. Discuss the procedure with the patient and assess the patient's ability to assist with the procedure.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates cooperation.
5. Place a cover over the sling of the bed scale.	Using a cover deters the spread of microorganisms.
6. Attach the sling to the bed scale. Lay the sheet or bath blanket in the sling. Turn on the scale. **Balance the scale so that weight reads 0.0.**	Scale will add the sling, blanket, and cover into the weight unless it is zeroed with the sling, blanket, and cover.
7. Adjust the bed to a comfortable working position (VHACEOSH, 2016). Position one caregiver on each side of the bed, if two caregivers are present. Raise side rail on the opposite side of the bed from where the scale is located, if not already in place. Cover the patient with the sheet or bath blanket. Remove other covers and any pillows.	Having the bed at the proper height prevents back and muscle strain. Having one caregiver on each side of the bed provides for patient safety and appropriate care. Side rail assists patient with movement. Blanket maintains patient's dignity and provides warmth.
8. Turn the patient onto their side facing the side rail, keeping their body covered with the sheet or blanket. Remove the sling from the scale. Place the cover on the sling. Roll cover and sling lengthwise. Place rolled sling under the patient, making sure the patient is centered in the sling.	Rolling the patient onto their side facilitates placing the patient onto the sling. Blanket maintains patient's dignity and provides warmth.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

9. Roll the patient back over the sling and onto the other side. Pull the sling through, as if placing sheet under patient, unrolling the sling as it is pulled through.	This facilitates placing the patient onto the sling.
10. Roll the scale over the bed so that the arms of the scale are directly over the patient. **Spread the base of the scale.** Lower the arms of the scale and place the arm hooks into the holes on the sling.	By spreading the base, you are giving the scale a wider base, thus preventing the scale from toppling over with the patient. Hooking sling to scale provides secure attachment to the scale and prevents injury.
11. Once the scale arms are hooked onto the sling, gradually elevate the sling so that the patient is lifted up off the bed (Figure 1). **Assess all tubes and drains, making sure that none have tension placed on them as the scale is lifted. Once the sling is no longer touching the bed, ensure that nothing else is hanging onto the sling (e.g., ventilator or IV tubing). If any tubing is connected to the patient, raise it up so that it is not adding any weight to the patient.**	The scale must be hanging free to obtain an accurate weight. Any tubing that is hanging off the scale will add weight to the patient.

FIGURE 1. Using a bed scale.

12. Note the weight reading on the scale. Slowly and gently, lower the patient back onto the bed. Disconnect the scale arms from the sling. Close the base of the scale and pull it away from the bed.	Lowering the patient slowly does not alarm the patient. Closing the base of the scale facilitates moving the scale.
13. Raise the side rail. Turn the patient to the side rail. Roll the sling up against the patient's backside.	Raising the side rail is a safety measure.
14. Raise the other side rail. Roll the patient back over the sling and up facing the other side rail. Remove the sling from the bed. Remove gloves, if used. Raise the remaining side rail. Perform hand hygiene.	The patient needs to be removed from the sling before it can be removed from the bed. Hand hygiene deters the spread of microorganisms.
15. Cover the patient and help them to a position of comfort. Place the bed in the lowest position.	Ensures patient comfort and safety.
16. Remove the disposable cover from the sling and discard in the appropriate receptacle.	Using a cover deters the spread of microorganisms.
17. Remove additional PPE, if used. Clean equipment based on facility policy. Perform hand	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Cleaning equipment prevents transmission of microorganisms. Hand hygiene deters the spread of microorganisms.

hygiene.

18.	Replace the scale and sling in the appropriate spot. Plug the scale into the electrical outlet.	Scale should be ready for use at any time.

DOCUMENTATION

Guidelines

Document weight, unit of measurement, and scale used.

Sample Documentation

10/15/25 0230 Patient reports pain in legs 5/10. Premedicated with oxycodone 5 mg and acetaminophen 325 mg 2 tabs PO before obtaining weight per order. Patient weighed using bed scale, 75.2 kg.
—M. Evans, RN

Developing Clinical Reasoning and Clinical Judgment

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *As the patient is being lifted, the scale begins to tip over:* Stop lifting the patient. Slowly lower the patient back to the bed. Ensure that the base of the scale is spread wide enough before attempting to weigh the patient.
- *Weight differs from the previous day's weight by more than 1 kg:* Weigh the patient using the same scale at the same time each day. Check scale calibration. Make sure that the patient is wearing the same clothing. Make sure that no tubes or containers are hanging on the scale. If the patient is incontinent, make sure undergarments are clean and dry.
- *Patient becomes agitated as the sling is raised into the air:* Stop lifting the patient and reassure them. If the patient continues to be agitated, lower them back to the bed. Reevaluate necessity of obtaining weight at that exact time.

Skill 27-2 Assessing the Neurologic, Musculoskeletal, and Peripheral Vascular Systems

DELEGATION CONSIDERATIONS

The assessment of the patient's neurologic, musculoskeletal, and peripheral vascular systems should not be delegated to assistive personnel (AP). Some items may be noticed while providing care and noted by the AP. The nurse must then validate, analyze, document, communicate, and act on these findings, as appropriate. Depending on the state's nurse practice act and the organization's policies and procedures, the licensed practical/vocational nurses (LPN/LVNs) may perform some or all the parts of assessment of the patient's neurologic, musculoskeletal, and peripheral vascular systems. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- PPE, as indicated
- Bath blanket or other drape
- Tongue depressor
- Examination gown
- Gloves
- Containers of odorous materials (e.g., coffee or chocolate), as indicated
- Miscellaneous items (e.g., pin, cotton, paper clip)
- Cotton-tipped applicators

IMPLEMENTATION

ACTION	RATIONALE

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

 1. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 2. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
3. Close the curtains around the bed and close the door to the room, if possible. Explain the purpose of the neurologic, musculoskeletal, and peripheral vascular examinations and what you are going to do. Answer any questions.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates cooperation.
4. Help the patient undress, if needed, and provide a patient gown. Assist the patient to a supine position, if possible. Use the bath blanket to cover any exposed area other than the one being assessed.	Having the patient wear a gown facilitates examination of the neurologic, musculoskeletal, and peripheral vascular systems. Use of a bath blanket provides for comfort and warmth.
5. Begin with a survey of the patient's overall hygiene and physical appearance.	This provides initial impressions of the patient. Hygiene and appearance can provide clues about the patient's mental state and comfort level.
6. Assess the patient's mental status.	
a. Evaluate level of consciousness.	This helps identify the patient's level of awareness.
b. Evaluate the patient's orientation to person, place, and time.	The patient should be awake and alert. Patients with altered level of consciousness may be lethargic, stuporous, or comatose.
c. Assess memory (immediate recall and past memory).	Memory problems may indicate neurologic impairment.
d. Evaluate the patient's ability to understand spoken and written word.	Evaluation of the patient's ability to understand spoken and written word helps assess for aphasia.
7. Test cranial nerve (CN) function, as indicated.	It is not necessary to assess every cranial nerve for every patient. Assessment should be individualized based on the patient's needs and health care setting and circumstances (Jensen, 2019).
a. Ask the patient to close the eyes, occlude one nostril, and then identify the smell of different substances, such as coffee, chocolate, or alcohol. Repeat with the other nostril.	This action tests the function of CN I (olfactory nerve).
b. Test visual acuity and pupillary constriction. Refer to previous discussion in the assessment of the head and neck.	This tests function of CN II and CN III (optic and oculomotor nerves).
c. Move the patient's eyes through the six cardinal positions of gaze. Refer to previous discussion in the assessment of the head and neck.	This testing evaluates the function of tests CN III, CN IV, and CN VI (oculomotor, trochlear, and abducens nerves).
d. Ask the patient to smile, frown, wrinkle the forehead, and puff out cheeks (Figure 1).	This maneuver evaluates the motor function of CN VII (facial nerve).

FIGURE 1. Puffing out cheeks.

e. Ask the patient to protrude tongue and push against the cheek with the tongue.	This evaluates function of CN XII (hypoglossal nerve).
f. Palpate the jaw muscles. Ask the patient to open and clench jaws. Stroke the patient's face with a cotton ball.	This evaluates function of CN V (trigeminal nerve).
g. Test hearing with the whispered voice test. Refer to previous discussion in the assessment of the head and neck.	This evaluates function of CN VIII (acoustic nerve).
h. Put on gloves. Ask patient to open mouth. While observing soft palate, ask patient to say "ah"; observe upward movement of the soft palate. Test the gag reflex by touching the posterior pharynx with the tongue depressor. Explain to patient that this may be uncomfortable. Ask the patient to swallow. Remove gloves.	Gloves prevent contact with blood and body fluids. An intact gag reflex and swallowing indicate normal functioning of CNs IX and X (glossopharyngeal and vagus nerves).
i. Place your hands on the patient's shoulders (Figure 2) while they shrug against resistance. Then place your hand on the patient's left cheek, then the right cheek, and have the patient push against it.	These actions check CN XI (spinal accessory nerve) function and trapezius and sternocleidomastoid muscle strength.
8. Check the patient's ability to move their neck. Ask the patient to touch their chin to the chest and to each shoulder, then move each ear to the corresponding shoulder (Figure 3), and then tip the head back as far as possible.	These actions assess neck ROM, which is normally smooth and controlled.

FIGURE 2. Assessing function of the spinal accessory nerve (CN XI) and muscular strength. (*Source:* From Weber, J. R., & Kelley, J. H. (2018). Health assessment in nursing [6th ed., p. 585]. Wolters Kluwer.)

FIGURE 3. Moving each ear to the corresponding shoulder. (*Source:* From Jensen, S. [2019]. Nursing health assessment [3rd ed., p. 601]. Wolters Kluwer.)

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

9. Inspect the upper extremities. Observe for skin color, presence of lesions, rashes, and muscle mass. Palpate for skin temperature, texture, and presence of masses.	Examination of the upper extremities provides information about the circulatory, integumentary, and musculoskeletal systems.
10. Ask the patient to extend arms forward and then rapidly turn palms up and down.	This maneuver tests proprioception and cerebellar function.
11. Ask the patient to flex upper arm and to resist examiner's opposing force (Figure 4).	This technique assesses the muscle strength of the upper extremities.

FIGURE 4. Assessing muscle strength of the upper extremities. (*Source:* From Jensen, S. [2019]. Nursing health assessment [3rd ed., p. 604]. Wolters Kluwer.)

12. Inspect and palpate the hands, fingers, wrists (Figure 5), and elbow joints.	Inspection and palpation provide information about abnormalities, tenderness, and ROM.
13. Ask the patient to bend and straighten the elbow, and flex and extend the wrists and hands.	This tests ROM of elbow joint and wrists.
14. Palpate the skin and the radial and brachial pulses. Assess the pulse rate, quality or amplitude, and rhythm. Test capillary refill.	Pulse palpation and capillary refill evaluate the peripheral vascular status of the upper extremities.
15. Cross your index and middle fingers. Have the patient squeeze your index and middle fingers (Figure 6).	This maneuver tests the muscle strength of the hands.

FIGURE 5. Palpating the wrist. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

FIGURE 6. Testing grip. Patient squeezes nurse's crossed index and middle fingers. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

16. Assist the patient to a supine position. Palpate (Figure 7A) and then use the bell of the stethoscope to auscultate the femoral pulses in the groin (Figure 7B), if not done during assessment of the abdomen. Note the strength of the pulse and grade it as with peripheral pulses.	This technique assesses flow of blood through the arteries. Auscultation can detect a bruit.

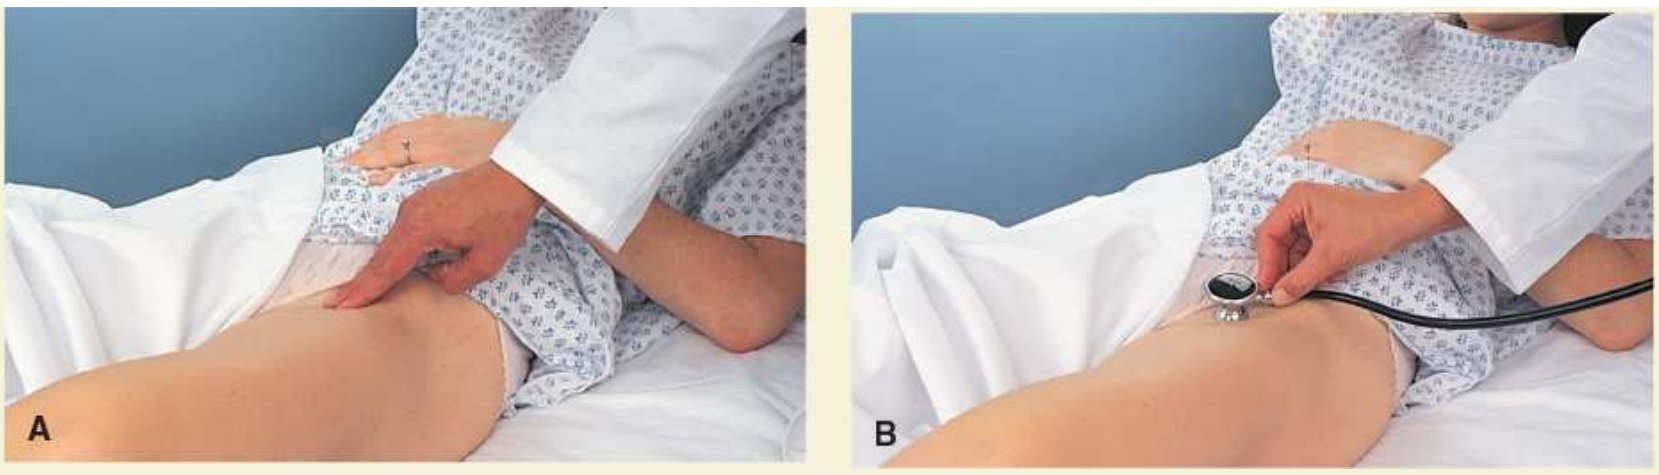

FIGURE 7. Palpating (**A**) and auscultating (**B**) the femoral pulses. (*Source:* Used with permission from Shutterstock. *Photos by B. Proud.*)

17. Examine the lower extremities. Inspect the legs and feet for color, lesions, varicosities, hair growth, nail growth, edema, and muscle mass.	Inspection provides information about peripheral vascular function.
18. Assess for pitting edema in the lower extremities by pressing fingers into the skin at the pretibial area and dorsum of the foot (Figure 8A). If an indentation remains in the skin after the fingers have been lifted, pitting edema is present (Figure 8B).	This technique reveals information about excess interstitial fluid. Refer to an edema scale in assessing the amount of edema: 1+ about 2 mm deep to 4+ about 8 mm deep.

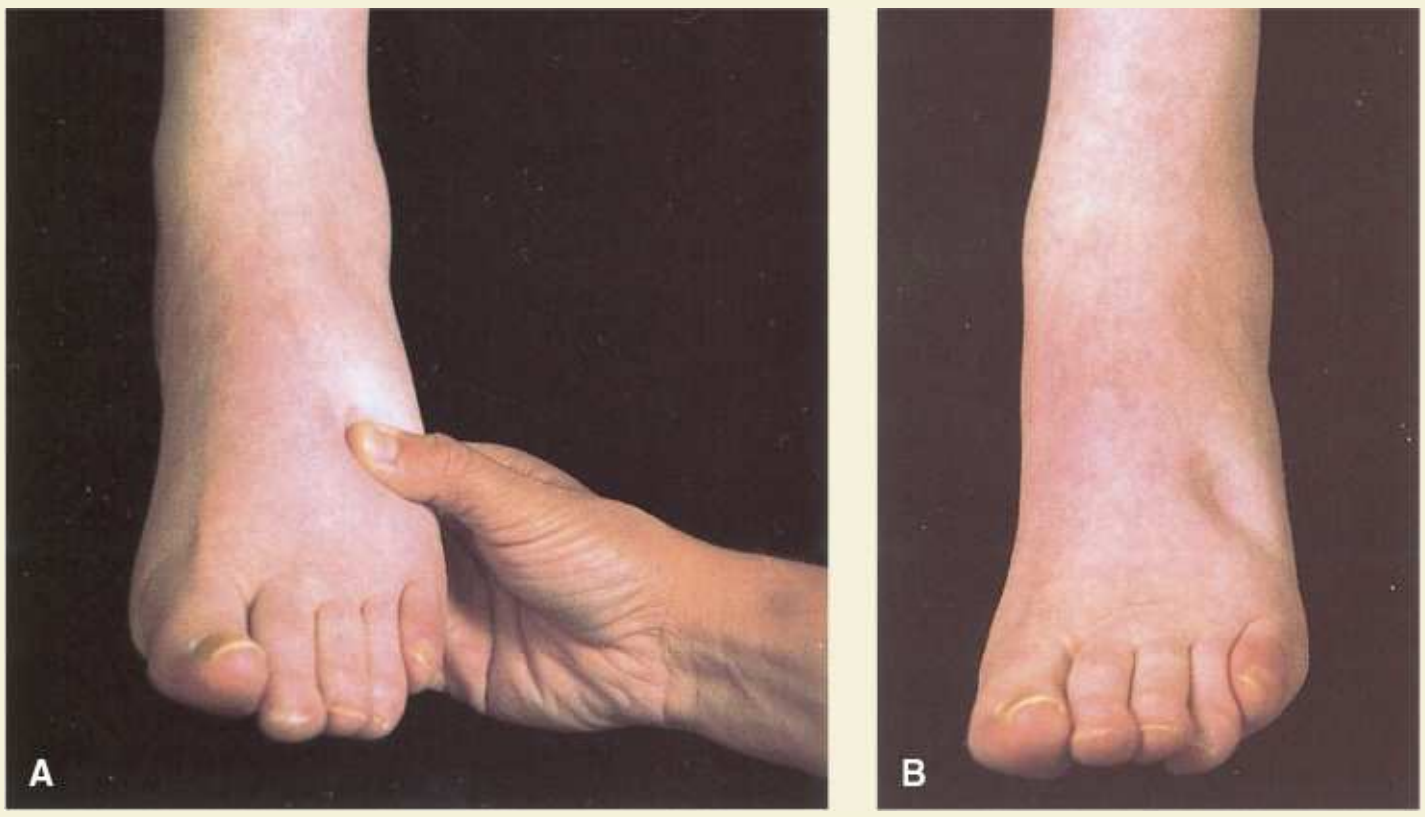

FIGURE 8. Assessing for pitting edema in lower extremities. (*Source:* From Hogan-Quigley, B., Palm, M. L., & Bickley, L. [2017]. Bates' nursing guide to physical examination and history taking [2nd ed., p. 453]. Wolters Kluwer.)

19. Palpate for pulses and skin temperature at the posterior tibial, dorsalis pedis, and popliteal areas. Assess the pulse rate, quality or amplitude, and rhythm. Test capillary refill.	Pulses, skin temperature, and capillary refill provide information about the patient's peripheral vascular status.
20. Ask the patient to move one leg laterally with the knee straight to test abduction of the hip. Keeping knee straight, move leg medially to test adduction of the hip. Repeat with other leg.	This maneuver assesses ROM and provides information about joint problems.
21. Ask the patient to raise the thigh against the resistance of your hand (Figure 9); next have the patient push outward against the resistance of your hand; then have the patient pull backward against the resistance of your hand. Repeat on the opposite side.	These measures assess motor strength of the upper and lower legs.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 9. Testing motor strength of upper leg. Patient attempts to raise thigh against nurse's resistance. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

22. Ask the patient to dorsiflex and then plantarflex both feet against opposing resistance (Figure 10).	These measure ankle flexion and dorsiflexion.

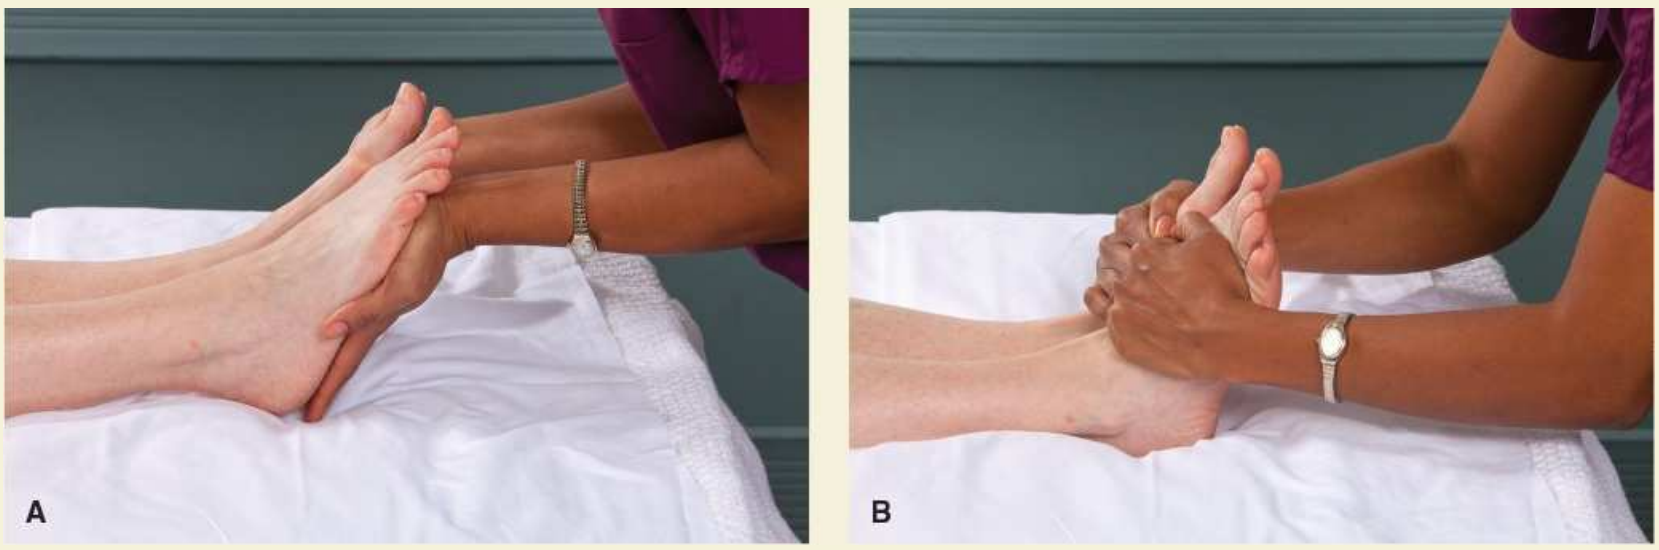

FIGURE 10. A. Testing ankle flexion and dorsiflexion. The patient first pushes the balls of the feet against resistance of the nurse's hands. **B.** Then attempts to pull against nurse's resistance. (*Source:* Used with permission from Shutterstock. *Photos by B. Proud.*)

23. As needed, assist the patient to a standing position. Observe the patient as they walk with a regular gait, on the toes, on the heels, and then heel to toe (Figure 11).	This procedure evaluates cerebellar and motor function.
24. Perform the Romberg's test; ask the patient to stand straight with feet together, both eyes closed with arms at side (Figure 12). Wait 20 seconds and observe for patient swaying and ability to maintain balance. Be alert to prevent a patient fall or injury related to losing balance during this assessment.	This test checks cerebellar functioning and evaluates balance, equilibrium, and coordination. Slight swaying is normal, but patient should be able to maintain balance.
25. Assist the patient to a comfortable position.	This ensures the patient's comfort.

FIGURE 11. Testing heel to toe walking. (*Source:* From Jensen, S. [2019]. Nursing health assessment [3rd ed., p. 652]. Wolters Kluwer.)

FIGURE 12. Positioning for the Romberg's test. (*Source:* From Jensen, S. [2019]. Nursing health assessment [3rd ed., p. 653]. Wolters Kluwer.)

26. Remove PPE, if used. Perform hand hygiene. Continue with assessments of specific body systems, as appropriate, or indicated. Initiate appropriate referral to other health care providers for further evaluation, as indicated.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms. Additional assessments should be completed, as indicated, to evaluate the patient's health status. Intervention by other health care providers may be indicated to evaluate and treat the patient's health status.

DOCUMENTATION

Guidelines

Document assessment techniques performed, along with specific findings. Note the cognitive responses of the patient, the tested cranial nerves, and sensation and motor responses. Document any patient statements of pain, muscle weakness, or joint abnormality. Record findings, including color, turgor, temperature, pulses, and capillary refill.

Sample Documentation

Practice documenting assessment techniques and findings in *Lippincott DocuCare*.

4/4/25 Patient alert, oriented, cognitively appropriate. Full ROM of all joints. Muscles soft, firm, nontender, no atrophy. Patient states pain in right calf. Right calf skin paler tone and slightly cooler compared with left calf. Peripheral pulses 72, +2, regular rhythm, equal bilaterally; exception—right posterior tibial and dorsalis pedis pulses +1. Capillary refill right lower extremity sluggish, >3 seconds, +sensation in feet, equal bilaterally.

—S. Moses, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

SPECIAL CONSIDERATIONS

General Considerations

- Before performing the mental status examination, inform the patient that some of the questions may seem unusual, but that you are attempting to evaluate overall cognitive function.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Infant and Child Considerations

- In an infant, jerky and brief twitching of the extremities may be noted and considered a normal finding.
- The Babinski sign is a normal finding in children age 24 months and younger (Jensen, 2019).
- The infant's extremities move symmetrically through ROM but lack full extension.
- Motor control develops in head, neck, trunk, and extremities in sequence.
- Coordination of movement varies according to the developmental level of the young child.

Older Adult Considerations

- Be aware that short-term memory, such as recall of recent events, may diminish with age. Older adults may also experience slowed reaction time as well.
- In the older adult patient, expect to find decreased musculoskeletal function, such as loss of muscle strength.
- Slower gait, with a wider base and flexed hips and knees.
- Keep in mind that older adults may take longer to perform certain actions, such as completing activities for testing coordination.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Describe how you would explain a cardiovascular assessment to the following patients:

- A healthy 5-year-old
- A college student who has never been ill
- A 50-year-old man who has never had a physical assessment
- An 85-year-old woman with heart problems

. When you are conducting a health history, your patient gives you strange answers. Later, during the mental status assessment, she gives you the wrong answers for the date and place. She also cannot remember what medications she takes. How would you document this information? What would you do next?

. When you make a home visit to conduct an initial health history and physical assessment, the patient refuses to let you do more than assess vital signs. What would you do?

PRACTICING FOR NCLEX

. A nurse on a medical-surgical unit is caring for a group of patients. For which patient will the nurse perform a focused assessment?

a. Newly admitted
b. Recent application of a wrist cast
c. Signs of acute respiratory distress
d. Post-abdominal surgery without complications

. A nurse admitting a patient to a long-term care facility performs a functional assessment. Which questions will the nurse include as part of the assessment? Select all that apply.

a. "Are you able to dress yourself?"
b. "Do you have a history of smoking?"
c. "What is the problem for which you are seeking care?"
d. "Do you prepare your own meals?"
e. "Do you manage your own finances?"
f. "Whom do you rely on for support?"

. A nurse in the neurology clinic is assessing a patient's eyes for extraocular movements. Which correctly describes the procedure for this test?

a. Ask the patient to sit about 3 ft away, facing the nurse.
b. Have the patient follow a penlight held 1 ft from their face slowly through the cardinal positions.
c. Move a penlight in concentric circular motion in front of the patient's eyes.
d. Ask the patient to cover one eye with a hand or index card.

. A nursing student is learning to perform physical assessments. When will the student use the technique of palpation? Select all that apply.

a. Assessing temperature of a patient's feet
b. Counting the apical pulse
c. Assessing for skin turgor
d. Evaluating lymph nodes

e. Assessing for dullness over a tumor
f. Finding a heart murmur

. When inspecting the skin of a patient who has cirrhosis of the liver, the nurse notes the skin has a yellow tint. What term will the nurse use to document the skin assessment in the electronic health record?

a. Jaundice
b. Cyanosis
c. Erythema
d. Pallor

. The nurse places a patient in the dorsal recumbent position during a physical assessment. Which nursing assessments can the nurse perform with the patient in this position? Select all that apply.

a. Assessing the abdomen
b. Taking peripheral pulses
c. Performing a breast examination
d. Auscultating the heart
e. Assessing vital signs
f. Assessing balance and gait

. A school nurse assesses adolescents' visual acuity using a Snellen eye chart. Which explanation does the nurse provide to the student whose vision is 20/40 in both eyes?

a. "They see better than 50% of people."
b. "Double vision is present."
c. "Vision is less than normal."
d. "They have normal vision."

. The nurse is caring for a patient experiencing bronchospasm due to an exacerbation of asthma. During auscultation, the nurse anticipates the presence of which breath sound?

a. Sibilant
b. Wheezes
c. Rhonchi
d. Crackles

. A nurse in the emergency department is using the Glasgow coma scale to assess a patient who was struck in the head and upper body with a baseball bat. Based on the information in the neurologic assessment, what numerical value will the nurse assign?
Electronic heath record (EHR)
Neurologic assessment
The patient opens his eyes to painful stimulus, does not speak, and withdraws to painful stimulus. Unable to assess orientation to person, time, and place.

a. 3
b. 7
c. 11
d. 15

. A nurse is caring for a patient with exacerbation of COPD and pneumonia. When auscultating the lungs, coarse expiratory, low-pitched, and continuous sounds that clear with coughing are present. How will the nurse document this breath sound in the electronic health record?

a. Rhonchi
b. Bronchovesicular breath sounds
c. Stridor
d. Bronchial breath sounds

. A nurse is assessing a patient's eyes for accommodation. Place the steps of this assessment in order they are performed.

a. Document the results in the electronic health record.
b. As the patient to look at a distant object, then back to the object held.
c. Hold a straight object 0 to 15 cm (4 to 6 inches) from the bridge of the patient's nose.
d. Observe for pupillary constriction when looking at the near object and for pupillary dilation when looking at the distant object held.
e. Ask the patient to look at the object.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

. A nurse is performing a breast assessment using the circular technique for palpation, gently compressing the breast tissue against the chest wall. How does the nurse proceed with the examination?

a. Begins at the tail of Spence and moves in increasing smaller circles
b. Starts at the outer edge of the breast and palpates up and down the breast
c. Works in a counterclockwise direction and palpates from the periphery toward the areola
d. Proceeds from the inner edge of the breast and palpates up and down the breast

. During physical assessment, a nurse inspects a patient's abdomen. What assessment technique does the nurse perform next?

a. Percussion
b. Palpation
c. Auscultation
d. Whichever provides patient comfort

. A nurse and AP are caring for a patient who just returned from the operating room after a femoral–popliteal arterial bypass graft. The nurse is getting another admission. What activity can the nurse safely delegate to the AP?

a. Determining if pedal pulses are present
b. Evaluating the patient's pain
c. Reinforcing the sterile dressing
d. Ordering dressing supplies

. A patient has come to the emergency department with symptoms of a stroke. During the assessment, the nurse asks the patient to raise their eyebrows, smile, and show their teeth to evaluate which cranial nerve?

a. Olfactory
b. Optic
c. Facial
d. Vagus

ANSWERS WITH RATIONALES

. **b.** After application of a cast, the nurse performs a focused neurovascular assessment, to assess circulation, sensation, and motor ability. A newly admitted patient requires a comprehensive assessment. The nurse performs an emergency assessment on a patient who presents with signs of acute respiratory difficulty. A postoperative patient without complications will receive ongoing assessments at regular intervals to evaluate the effectiveness of care and to assess for new problems.

. **a, d, e.** A functional health assessment including strengths and areas needing improvement focuses on the effects of health or illness on a patient's quality of life. Questions about the patient's ability to perform ADLs and IADLs such as dressing, grooming, preparing meals, and managing finances are included. A history of smoking is a lifestyle factor, and the chief complaint is the reason for seeking health care; both are assessed during the health history. Social networks and support psychosocial factors are also assessed during the health history.

. **b.** The steps in testing for extraocular movement are: (1) Ask the patient to sit or stand about 2 ft away, facing the nurse, who is sitting or standing at eye level with the patient; (2) ask the patient to hold the head still and follow the movement of a forefinger or a penlight with the eyes; (3) keeping the finger or light about 1 foot from the patient's face, move it slowly through the cardinal positions of gaze—up and down, left and right, diagonally up and down to the left, diagonally up and down to the right.

. **a, c, d.** During palpation, the nurse uses the sense of touch to compare bilateral pulses for symmetrical temperature, assess skin turgor, and check for enlarged lymph nodes. During percussion, the fingertips are used to tap the body over body tissues to produce vibrations and sound waves. The characteristics of the sounds provide information about the location, shape, size, and density of tissues, such as dullness over a mass or fluid accumulation. Auscultation refers to listening with a stethoscope to sounds produced in the body; counting the apical pulse or auscultating heart sounds/murmurs are examples.

. **a.** Jaundice refers to a yellowish skin color caused by liver, gallbladder, or pancreatic exocrine diseases. Cyanosis is a bluish skin color caused by a cold environment or decreased oxygenation. Erythema is a reddish color caused by blushing, alcohol intake, fever, injury trauma, or infection. Pallor is a paleness caused by anemia or shock.

. **b, c, d.** In the dorsal recumbent position, the patient lies on the back with legs separated, knees flexed, and soles of the feet on the bed. It is used to assess the head, neck, anterior thorax, lungs, heart, breasts, extremities, and peripheral pulses. It should not be used for abdominal assessment because it causes contraction of the abdominal muscles. Vital sign assessment should be done in the sitting position, and evaluating balance and gait is done with the patient in the standing position.

. **c.** Normal vision is 20/20. The higher the denominator indicates increasingly worse vision; 20/40 vision indicates less

than normal vision.

. **d.** Wheezes are musical or squeaking high-pitched, continuous sounds heard as air passes through narrowed airways, such as with bronchospasm found in asthma or COPD. Rhonchi are low-pitched, continuous sounds with a snoring quality, which may clear with coughing; they occur when air passes through secretions. Crackles are discontinuous bubbling, cracking, or popping, low- to high-pitched sounds, that occur when air passes through fluid in the airways.

. **b.** Eye opening to painful stimulus = 2 points, no speech = 1 point; and withdrawal to painful stimulus = 4 points, for a total score of 7. A score of 8 or less is associated with coma.

. **a.** Rhonchi are abnormal low-pitched, continuous breath sounds auscultated during inspiration and occasionally expiration, indicating that air is passing through or around secretions. Bronchovesicular breath sounds are normal sounds heard on inspiration and expiration. Stridor is a harsh, loud, high-pitched sound auscultated on inspiration indicating narrowing of the upper airway or presence of a foreign body. Bronchial sounds are normal blowing, hollow sounds, auscultated over the larynx and trachea.

. **c, e, b, d, a.** To test accommodation the nurse holds the forefinger, a pencil, or other straight object about 10 to 15 cm (4 to 6 inches) from the bridge of the patient's nose. The patient is asked to look at the object, then at a distant object, then back to the object being held. The pupil normally constricts when looking at a near object and dilates when looking at a distant object. The patient must be cooperative to complete this assessment.

. **a.** During breast assessment, the nurse palpates each quadrant of the breasts in a systematic method using the pads of the first three fingers to gently compress the breast tissue against the chest wall. In the circular method, the nurse begins at the tail of Spence and move in increasingly smaller circles. In the wedge method, the nurse works in a clockwise direction and palpates from the periphery toward the areola. In the vertical strip method, the nurse begins at the outer edge of the breast, palpating up and down the breast.

. **c.** When assessing the abdomen, the sequence for assessment is: inspection, auscultation, percussion, and palpation. Auscultation follows inspection to avoid stimulating bowel sounds during percussion.

. **b.** The nurse can delegate noncomplex activities to the AP such as obtaining (dressing) supplies, bedmaking, bathing, I & O, toileting, and ambulation. The nurse must perform assessments, provide teaching, perform sterile procedures, and develop the care plan.

. **c.** Motor function of the facial nerve (cranial nerve VII) is assessed by asking the patient to raise their eyebrow, smile, and show their teeth. The olfactory nerve (cranial nerve I) is tested by testing the sense of smell using various familiar substances. The nurse tests the optic nerve (cranial nerve II) for acuity and visual fields and the vagus nerve (cranial nerve X) by asking the patient to swallow and speak, noting hoarseness.

Safety, Security, and Emergency Preparedness

Kara Greenwood

Kara, a high school junior class representative and peer counselor, comes to the local community health center for a routine examination. During the interview, she says, “My guidance counselor has asked me and a few of my friends to develop a talk for our classmates on the dangers we face as adolescents. I know everybody is worried about terrorism, but I want to make sure that we talk about other safety issues, too.”

Bessie Washington

Bessie, a 77-year-old woman, was recently discharged to her home after suffering a cerebrovascular accident (stroke). She lives alone in a small, one-bedroom apartment and uses a walker to ambulate. She says, “I have so much stuff crammed into this small apartment! I almost fell this morning going from my bedroom to the kitchen.”

Juanita and Inez Flores

Juanita is a young mother of a 1-year-old girl, Inez. Today, they are at the clinic for a well-child visit. Juanita is sitting on a cot with her daughter, whose legs are dangling off the edge of the cot, about a foot above ground level. Juanita turns to get something out of her purse when Inez falls to the floor and begins to cry loudly.

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Identify person-centered aspects of safety and security.
. Identify patients at risk for injury.
. Describe specific safety risk factors for each developmental stage.
. Select nursing diagnoses for patients in unsafe situations.
. Describe health-teaching interventions to promote safety for each developmental stage.
. Describe strategies to decrease the risk for injury in the home.
. Describe systems-based aspects of safety and security, specifically in relation to the health care setting.
. Articulate population-based aspects of safety and security.
. Explore resources for developing and evaluating an emergency management plan.
. Evaluate the effectiveness of safety interventions.

safety event report
sentinel event

Safety and security are basic human needs. **Safety**—or freedom from danger, harm, or risk—is a paramount concern that underlies all nursing care. In addition, individual patient safety is a responsibility of all health care providers. The Institute of Medicine (IOM; renamed National Academy of Sciences, Engineering, and Medicines in 2015) report *To Err is Human*, introduced in 2000, recognized the need for a renewed focus on a culture of safety that promotes safe, effective, person-centered delivery of care. The IOM identified safety as an organizational priority and emphasized that medical errors are more frequently due to system problems rather than human error. Evidence-based research has identified tools and techniques designed to facilitate the elimination of errors and promote a safer health care environment (U.S. Department of Labor, OSHA, 2016). However, the impact each person has on the collective development of a culture of safety should not be minimized. Since nurses comprise the largest number of health care workers, their role is prominent and they have an unparalleled opportunity to influence the lives of their patients. The American Nurses Association (ANA) defines a **culture of safety** as an organizational environment where "core values and behaviors—resulting from a collective and sustained commitment by organizational leadership, manager and workers—emphasize safety over competing goals" (ANA, n.d.b, para 3). This idea of a culture of safety originated in the business world, but has been translated to health care and includes these key features: (1) acknowledgment of the high-risk nature of health care and the commitment to safe operations, (2) maintenance of a blame-free environment where reporting is protected and expected, (3) promotion of teamwork and collaboration to prevent and seek solutions to patient safety issues, and (4) a systems-based perspective where the organization commits resources to address actual/potential safety issues (U.S. Department of Health and Human Services, Agency for Healthcare Research and Quality, 2019a). Safety is a focus in all health care facilities as well as in the home, workplace, and community. Many safety and security concerns are universal for all age groups, but there are unique considerations for each developmental stage. We will focus on the nurse's role in individual-person-centered and system-based aspects of safety in the first two parts of this chapter.

In addition to consideration at the individual and health care systems levels, safety and security in the broader sense of our community will be explored in the third part of this chapter. Since the mass casualties that occurred in the terrorist attacks of September 11, 2001, as well as terrorist attacks around the world since then and the pandemic, the health care community has become increasingly aware of the need to be prepared should future incidents occur. Nurses are a vital part of any emergency response team and need knowledge about biologic, chemical, and radioactive agents as well as the skills and competencies required to respond safely and effectively.

The Institute for Healthcare Improvement (IHI, 2020) convened a steering committee comprising 27 national organizations to devise *A National Action Plan to Advance Patient Safety* and an associated assessment plan and implementation resource guide. The four foundational and interconnected areas identified for collaboration include: (1) culture, leadership and governance by leaders, governing bodies, and policymakers focused on safety; (2) patient and family engagement that includes partnering in all aspects of their care; (3) workforce safety and resilience using a systems perspective; and (4) establishing a network that supports continuous learning and information sharing. This call to action and associated competencies connect person-centered care, the systems perspective, and population health in an effort to advance patient safety.

This chapter provides practical information on the nurse's role in addressing safety and security from the person-centered, system, and population perspectives. Safety is one of the foundational principles of nursing care—watch for examples related to safety throughout this textbook and reflect on the clear application of principles related to safety in the situations presented in each chapter. Understanding the fundamental principles of safety and security provides the basis for the delivery of nursing care and should guide your thinking as a member of the profession. (See the accompanying Reflective Practice box.)

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO ETHICAL AND LEGAL SKILLS

I first met Juanita Flores while working at a children's hospital two summers ago in a nurse externship program. Juanita was the mother of a 1-year-old girl, Inez, who had been diagnosed with failure to thrive and had been on the rehabilitation unit for some time. The child was very small and had a feeding program prescribed. One day while I was in the room, Juanita was sitting on the cot with her daughter, whose legs were dangling off the edge of the cot, about 1 foot above ground level. I was taking the child's vital signs. As the mother turned her back for a minute to grab something from her bag, I turned away to wash my hands in the sink. All of a sudden, I heard a thud and crying as Inez fell to the floor. Juanita tried to comfort her, picking her up and rocking and singing to her. Although I knew it was not completely my fault, I felt horrible about turning my back on the child for only a few seconds to wash my hands. Although Juanita

and I were both in the room, the child had been left unsupervised. I was not watching Inez for only a few seconds … and she fell. I wanted to tell my preceptor right away and knew I *should* in case anything had happened to the child, but I was nervous and afraid that I would get into trouble.

Thinking Outside the Box: Possible Courses of Action

- Tell my preceptor immediately that the child had fallen, and risk being asked why I had turned my back on the child.
- Report later that morning that the child had fallen earlier, and not make a big deal of it.
- Not mention it at all.

Evaluating a Good Outcome: How Do I Define Success?

- Patient benefits from my actions, or at least is not harmed.
- My professional integrity is not compromised, nor is the personal integrity of the patient.
- A level of respect is maintained between the preceptor and student.
- Institutional policy for incident reporting is not violated.

Personal Learning: Here's to the Future!

Although I did tell my preceptor what had happened, I was not pleased by the way I handled the situation. Instead of reporting the incident right away, I waited until my preceptor was in the room with me, a half-hour or so later. I casually mentioned that the child had fallen earlier that morning but seemed to be fine. When my preceptor asked why I did not inform her earlier, I said that I couldn't find her and assumed that she was busy—plus, the child seemed fine and her mother was with her.

I was disappointed in how I dealt with this situation. Although I did not get formally reprimanded for the situation, an incident report was written documenting that the child had fallen. The health care provider also came to examine Inez to ensure that the child was indeed okay. My preceptor stressed the importance of reporting incidents as soon as they happen, rather than delaying or ignoring them. This time the child was uninjured, but I learned that in the future I will report any problem immediately. It is very important to follow the institution's policy for reporting incidents to ensure both your professional integrity and the well-being of the patient.

Anne Hrynko, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? Is the nurse extern's fear justification for the action? Please explain. What ethical and legal principles, if any, were violated in this situation? What liability would the nurse extern be required to assume? Can you think of other ways to respond? What knowledge, skills, and attitudes do you need to develop to continuously improve quality and safety when caring for patients like Juanita and Inez Flores?

Patient-Centered Care: How might the nurse extern have interacted with the mother to promote the child's safety? What information should the nurse extern discuss with Juanita Flores concerning providing a safe environment for her child at various developmental stages? How could the nurse extern further involve the mother as a partner in maintaining safety through all hospital encounters?

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to improve to ensure that you function as a member of the patient care team and minimize risk of harm to patients? How do you think this incident affected the relationship between the nurse extern and her preceptor?

Safety/Evidence-Based Practice: How might the delay in reporting the child's fall have affected the outcome of this situation? Should the extern initiate a discussion with her preceptor to review personal accountability and reporting procedures in a timely manner for any safety violations or incidents? What evidence in nursing literature provides guidance for decision making regarding ensuring a safe patient care environment? Given the focus on a culture of safety, should the health care team review what went wrong to allow this incident to occur, rather than who let it happen?

Informatics: Can you identify essential information that must be documented in the child's electronic health record regarding the fall she experienced? What other actions should be documented regarding the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

institution's response to the incident?

PERSON-CENTERED ASPECTS OF SAFETY AND SECURITY

Promoting safety and preventing injury are dual responsibilities of the nurse. Being aware of individual factors that affect a patient's safety, such as developmental level, lifestyle, mobility, sensory perception, knowledge level, communication ability, physical health state, and psychosocial state allows nurses to identify potential hazards and promote wellness. Injuries and deaths from motor vehicle accidents, falls, fire, suffocation, poisoning, and abuse/interpersonal violence occur with alarming regularity across the lifespan, but they tend to be associated with a specific age group/developmental level. Many of these injuries and deaths can be prevented with appropriate safety awareness and precautions. Patient safety is integral to the nursing plan of care. It is important to empower patients to make changes to their own environment, but depending on the situation, nurses may need to intervene in order to control or modify the patient's environment.

DEVELOPMENTAL CONSIDERATIONS

Each developmental level carries its own particular risks. Physical and cognitive changes reflect the sequential developmental stages of infancy through older adulthood. Health care needs and safety risks change as people progress from infancy to the older adult stage. For children, potential hazards multiply as their motor skills develop and their environment expands. Nurses promote safe sleeping practices for infants when they advise parents and caregivers to avoid stuffed animals and crib bumpers that increase the risk for suffocation. The risk of falling is noticeably higher for children. Toddlers are increasingly active and need appropriate safeguards to prevent falls in the home. Outdoor play and the associated injuries become an issue in the years between toddlerhood and adolescence. Adolescents face great dangers when they take illegal drugs, drink alcohol, take medications not prescribed for them, or engage in sex without a condom. These unsafe behaviors can result in alcohol-related motor vehicle accidents, pregnancy, and sexually transmitted diseases. Drug and/or alcohol use disorders are a concern for young and middle-aged adults employed in stressful work environments. Older adults experiencing altered balance or decline in cognitive abilities are increasingly vulnerable to falls and episodes of confusion. Nurses have first-hand experience with the specific hazards confronting each age group and situation. Education to promote awareness of potentially dangerous situations must begin as early as possible and continue throughout the lifespan.

Prompt recognition of a potential or actual threat to safety is crucial; the nursing assessment may play a vital role in identifying hazards in the environment. Teaching Tips 28-1 lists common types of safety risks according to developmental age, along with sample teaching tips to discuss with patients and families. Although some risks are universal and occur across the lifespan, developmental stages need to be considered when developing a safety teaching plan.

Neonate and Infant

FETAL CONSIDERATIONS

Safety considerations begin with an awareness of behaviors that may harm the developing fetus. Newborns of mothers who smoke have a lower birth weight. Excessive alcohol consumption and use of drugs may cause adverse effects that are readily apparent at birth. Reinforce a pregnant person's knowledge of the risks associated with excess alcohol consumption, smoking, drug use, and exposure to other dangers in the environment (Centers for Disease Control and Prevention [CDC], 2020d). It is also important to stress the importance of regular prenatal visits and the use of prenatal vitamins.

MOBILITY

The nurse has many opportunities to educate parents/caregivers about safety and accident prevention for infants. Young infants' lack of mobility limits opportunities for hazardous activity, but safeguards are vital to prevent accidents. Safe care includes never leaving the infant unattended, using crib rails, and monitoring the setting for objects that the infant could place in the mouth and swallow. As the child becomes more active, parents and caregivers must be alert to hazards that a curious, mobile child may encounter. All items within reach must be carefully inspected and, if dangerous, kept in a safe place, out of the child's reach. Because infants frequently climb or pull up on objects, hot liquids and sharp instruments must be placed out of their reach. Also, remind parents/caregivers that items that are small enough to fit through a standard toilet paper tube represent a potential choking hazard for young children.

CAR SEATS

All 50 states mandate the use of infant carriers and car seats when transporting a child in a motor vehicle. In 2018, the American Academy of Pediatrics (AAP) reaffirmed published guidelines recommending that infants and toddlers remain in a rear-facing safety seat until they reach the highest height or weight allowed by the car safety seat manufacturer. This

position provides more support for the head, neck, and spine should a crash occur. Children should then progress to a forward-facing seat with a five-point harness until they reach the maximum height and weight limit for that seat. Children should use a belt-positioning booster seat until they are 4 ft, 9 inches tall and between 8 and 12 years old (80 to 100 lb). Due to the force of a deployed airbag, sitting in the front seat is not recommended until the child is 13 years old (Durbin et al., 2018). If no other arrangement is possible and an older child must ride in the front seat, move the vehicle seat as far back as possible away from the air bag and restrain the child properly based on the child's size. Most parents/caregivers do not secure the car seat tightly enough with the seat belt or latch system, or they fail to tighten the car seat's harness straps. These seemingly simple omissions can lead to tragic consequences.

Teaching Tips 28-1

PREVENTING ACCIDENTS AND PROMOTING SAFETY AT VARYING DEVELOPMENTAL STAGES

Developmental Stage/Safety Risks	Teaching Tip	Why This Is Important
Fetus Abnormal growth and development	• Abstain from alcohol and caffeine while pregnant. • Stop smoking or reduce the number of cigarettes smoked per day. • Avoid all drugs, including OTC drugs, unless prescribed by a health care provider. • Avoid exposure to pesticides and certain environmental chemicals. • Avoid exposure to radiation.	Any factors, chemical or physical, can adversely affect the fertilized ovum, embryo, and developing fetus. A fetus is extremely vulnerable to environmental hazards.
Neonate (first 28 days of life) Infection Falls Accidental suffocation and strangulation in bed (ASSB)	• Wash hands frequently. • Never leave infant unsupervised on a raised surface without side rails. • Use appropriate infant car seat that is secured in the back seat facing the rear of the car. • Handle infant securely while supporting the head. • Place infant on back to sleep.	Physical care for the newborn includes maintaining a patent airway, protecting the baby from infection and injury, and providing optimal nutrition.
Infant Falls Injuries from toys Burns Suffocation or drowning Inhalation or ingestion of foreign bodies	• Supervise child closely to prevent injury. • Select toys appropriate for developmental level. • Use appropriate safety equipment in the home (e.g., locks for cabinets, gates, electrical outlet covers). • Never leave child alone in the bathtub. • Childproof the entire house.	Infants progress from rolling over to sitting, crawling, and pulling up to stand. They are very curious and will explore everything in their environment that they can.
Toddler Falls Cuts from sharp objects Burns Suffocation or drowning Inhalation or ingestion of foreign bodies/poisons	• Have poison control center phone number in readily accessible location. • Use appropriate car seat for toddler. • Supervise child closely to prevent injury. • Childproof house to ensure that poisonous products, drugs, guns, and small objects are out of toddler's reach. • Never leave child alone and unsupervised outside. • Keep all hot items on stove out of child's reach.	Toddlers accomplish a wide variety of developmental tasks and progress to walking and talking. They become more independent and continue to explore their environment.
Preschooler Falls	• Teach child to wear proper safety equipment when riding bicycles or	Though more independent, preschoolers still have an immature understanding

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Cuts Burns Drowning Inhalation or ingestion Guns and weapons	scooters. • Ensure that playing areas are safe. • Begin to teach safety measures to child. • Do not leave child alone in the bathtub or near water. • Practice emergency evacuation measures. • Teach about fire safety.	of dangerous behavior. They may strive to imitate adults and thus attempt dangerous behavior.
School-Age Child Burns Drowning Broken bones Concussions (TBI) Inhalation or ingestion Guns and weapons Substance use Bullying	• Teach accident prevention at school and home. • Teach child to wear safety equipment when playing sports and when riding a bicycle. • Reinforce teaching about symptoms that require immediate medical attention. • Continue immunizations as scheduled. • Provide drug, alcohol, and sex education. • Reinforce use of seat belts and pedestrian safety. • Support social relationships and watch for changes in the child that may indicate bullying or being bullied.	School-age children have developed more refined muscular coordination, but increasing involvement in sports and play activities increases their risk for injury. TBI can cause disruption in brain function and death. Cognitive maturity improves their ability to understand safety instructions.
Adolescent Motor vehicle accidents Drowning Guns and weapons Inhalation and ingestion Bullying	• Teach responsibilities of new freedoms that accompany being a teenager. • Enroll teen in safety courses (driver education, water safety, emergency care measures). • Emphasize gun safety. • Get physical examination before participating in sports. • Make time to listen to and talk with your adolescent (helps with stress reduction). • Follow healthy lifestyle (nutrition, rest, etc.). • Teach about sexuality, intercourse, sexually transmitted diseases, and birth control. • Encourage child to report any sexual harassment or abuse of any kind. • Engage in open dialogue about events relative to social media, personal relationships, and school activities.	Adolescence is a critical period in growth and development. The adolescent needs increasing freedom and responsibility to prepare for adulthood. During this time, the mind has a great ability to acquire and use knowledge. The teen’s peer group is a greater influence than families during this stage.
Adult Stress Domestic violence Motor vehicle accidents Industrial accidents Drug and alcohol use disorders	• Practice stress reduction techniques (e.g., meditation, exercise). • Enroll in a defensive driving course. • Evaluate the workplace for safety hazards and utilize safety equipment as prescribed. • Practice moderation when consuming alcohol. • Avoid use of illegal drugs. • Provide options and referrals to those experiencing intimate partner violence (IPV).	As people progress through the adult years, visible signs of aging become apparent. Lifestyle behaviors and situational or family crises can also impact an adult’s overall health and cause stress. Preventive health practices help adults improve the quality and duration of life.

Older Adult Falls Motor vehicle accidents Elder abuse Sensorimotor changes Fires	• Identify safety hazards in the environment. • Modify the environment as necessary. • Attend defensive driving courses or courses designed for older drivers. • Encourage regular vision and hearing tests. • If prescribed, ensure that eyeglasses and hearing aids are available and functioning. • Wear appropriate footwear. • Have operational smoke detectors in place. • Objectively document and report any signs of neglect and abuse.	Accidental injuries occur more frequently in older adults because of decreased sensory abilities, slower reflexes and reaction times, changes in hearing and vision, and loss of strength and mobility. Collaboration between family and health care providers can ensure a safe, comfortable environment, and promote healthy aging.

Toddler and Preschooler

ENVIRONMENT

To prevent accidental injury and death in toddlers and preschoolers, parents/caregivers need to consider the environment. Play areas should allow for exploration, but still provide for safety. Children's overconfidence, curiosity, and impulsiveness make them more likely to dart into the street while chasing a ball, climb into a discarded refrigerator, or play with matches. Vigilant supervision by parents/caregivers should anticipate hazards in the environment, protect the child, and capitalize of teaching moments to model and instill good decision making in the child. Childproofing products are available that help parents/caregivers and children recognize dangerous items in the home and prevent injury. **Poison control centers (PCCs)** provide checklists for poison proofing a home and provide lists of toxic household items. Such lists are helpful when assessing and teaching the family about poisonous materials (see Box 28-1).

POISONING

Ingestion of poisons or medications is a major threat for preschoolers, due in part to the unprecedented amount of medication in the average home today. Concerted efforts by people, communities, state governments, and the federal government have reduced the number of accidental deaths by poisoning. The **PR**evention of **O**verdoses and **T**reatment **E**rrors in **C**hildren **T**askforce (PROTECT) Initiative is one collaborative among public health agencies, private companies, professional organizations, consumer/patient advocates, and other experts focused on developing strategies to keep children safe from unintentional medication overdoses. Their focus is on a three-pronged approach involving safer (child-resistant) packaging, safer use, and safer storage (CDC, 2020g). Although the number of children seen in the emergency department (ED) has steadily decreased since it peaked in 2010, each year, more than 47,500 children younger than age 6 years are treated for accidental poisoning from ingestion of medications (Safe Kids Worldwide, 2020). Dosing errors constitute fewer of the medication cases and involve giving the medication twice by mistake, giving the medication doses too close together, giving the incorrect dose, confusing the units of measurement, and using the dispensing cup incorrectly (Safe Kids Worldwide, 2020). Factors that put children most at risk for exposure to toxic substances include unsafe storage in the home, spending time in environments other than the home, lack of attention on the part of the caregiver, the rise in multigenerational families, and the presence of multiple pharmaceuticals, vitamins, and dietary supplements in the home (Safe Kids Worldwide, 2020).

Box 28-1 **Home Safety Checklist**

Fire and Burn Safety

- ☐ Have a list of emergency phone numbers posted near the phone.
- ☐ Install smoke detectors in each room (or at a minimum, on each floor).
- ☐ Replace smoke detector batteries when you reset your clock.
- ☐ Have a fire extinguisher available on each floor and know how to use it.
- ☐ Practice a fire escape plan with your family.
- ☐ Teach all family members to stop, drop, and roll if clothing catches on fire.
- ☐ Keep matches and lighters out of children's reach.
- ☐ Keep lighted candles out of children's reach.
- ☐ Buy flame-resistant children's clothing, particularly sleepwear.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Keep bedroom doors closed while sleeping (use monitor to listen for a child).
- Have ashtrays readily available if there is a smoker in the house.
- Enforce a strict “no smoking in bed” policy.
- After a party, check wastebaskets, ashtrays, furniture, and carpets for carelessly discarded cigarettes.
- Turn off a kerosene heater when no one is in the room and at bedtime.
- Operate your fireplace or wood-burning stove safely (flue open, fire screen covering the opening, annual chimney cleaning, proper disposal of ashes).
- Prevent trash or paint-saturated rags from accumulating in your garage.
- Store oily rags, gasoline, or other flammables away from heating sources or open flames, such as the pilot light of the water heater.
- Cook on back burners and turn pot handles toward the back of the stove.
- Keep hot dishes away from the edges of tables and counters.
- Set water heater at a safe temperature (below 120°F).
- Check bath water temperature with the back of your wrist before placing a child in bath.
- Use sunscreen and protective clothing to minimize exposure to the sun and prevent sunburn.

Electrical Safety

- Maintain electrical cords in good condition.
- Protect unused electric outlets with safety covers.
- Use the proper replacement for a blown fuse.
- Keep an electric space heater away from curtains and flammable material.
- Turn off appliances before going to bed or leaving the house.
- Hire a professional to do electrical repairs.
- Never overload wall outlets or extension cords.
- Unplug appliances that are not in use.
- Do not permit young children to use the microwave.

Preventing Poisoning

- Keep the phone number for the local poison control center next to the phone.
- Color-code medication bottles for those who are visually impaired.
- Syrup of ipecac is no longer recommended if poisoning should occur. Immediately contact the Poison Control Center (1-800-222-1222).
- Store all medicines in child-resistant containers in a locked medicine cabinet.
- Destroy old medicines (flush down the toilet or drop off at appropriate facilities).
- Keep all poisonous plants out of a child’s reach.
- Avoid eating any fresh or prepared foods that look or smell spoiled.
- Store cleaning products, insecticides, and corrosives safely out of a child’s reach.
- Avoid mixing caustic products with any other household product (dangerous chemical reactions may occur).
- Keep shampoos and cosmetics in a safe place.
- Use safety latches on cabinets.
- Store alcoholic beverages out of a child’s reach.
- Check that paint or finish on furniture and toys is nontoxic.
- Install a carbon monoxide detector in your home.
- Have your furnace professionally inspected each year.
- Keep vents and chimneys clear of debris and have them checked seasonally.
- Don’t operate cars, motorized equipment, or charcoal or gas grills in enclosed spaces.

Preventing Falls and Other Injuries

- Keep stairways clear and uncluttered.
- Maintain walkways, stairs, and railings in good repair.
- Keep stairs, hallways, outside walkways, and working areas well lit.
- Install safety gates at tops and bottoms of stairways.
- Paint the bottom step of the stairs a different color.
- Apply nonslip adhesive strips to the bottom surface of the tub or shower.
- Have a raised toilet seat with support arms available if necessary.
- Provide grab bars next to the toilet and in the tub or shower area.
- Use sturdy chairs that have armrests.
- Eliminate scatter rugs or secure them with adhesive strips on the underside.
- Use a handheld device, such as pincers, when reaching for inaccessible items.

- Buckle a child into an approved automobile safety seat even when making short trips.

Firearm Safety

- Keep guns and ammunition stored separately and locked up.
- Install trigger locks on all guns.
- Make certain that the key to the locked gun storage area is not available to a child.
- Discuss the risk for injury from guns and gun safety with your children.
- Instruct your child never to touch a gun or remain in a friend's house where a gun is accessible.

Preventing Asphyxiation or Choking

- Keep plastic bags out of a child's reach.
- Check that crib slats are no more than 2 ⅜ inches apart.
- Ensure that the mattress fits the sides of the crib snugly.
- Remove soft pillows or thick blankets from your infant's crib.
- Never place an infant on a waterbed to sleep.
- Cut food into small pieces before giving it to a young child.
- Supervise young children when eating and drinking.
- Avoid giving peanuts, hard candy, or other small treats to a young child.
- Keep small objects, such as jewelry, buttons, and safety pins, out of a child's reach.
- Use toys appropriate for the child's age.
- Always watch a child who is in the tub.
- Cover wading pools and sandboxes when not in use.
- Check that nearby swimming pools are enclosed with a fence that your child cannot easily climb over.
- Keep pool rescue equipment nearby.
- Supervise your child closely when near water.
- Know how to perform cardiopulmonary resuscitation and the Heimlich maneuver.

Nursing interventions involve health education aimed at preventing accidental poisoning in the home. Every household must have the telephone number of the nearest PCC readily available. Emphasize that parents/caregivers should call the PCC immediately, before attempting any home remedy. Parents/caregivers may be instructed to bring the child immediately to an emergency facility for treatment. The focus of emergency treatment of poisoning is to stabilize vital body functions, prevent the absorption of the poison, and encourage excretion of the toxic substance.

Activated charcoal is considered the most effective agent for preventing absorption of the ingested toxin. It is not recommended for storage or use at home. Activated charcoal can be administered through a nasogastric tube in the ED for serious poisonings after the risks and benefits have been determined (Juurlink, 2016). Syrup of ipecac is no longer recommended because vomiting may be dangerous. A toxic substance may prove more hazardous coming up rather than when it was swallowed. Gastric lavage is no longer prescribed routinely for treatment of ingestion of a toxic substance because it may propel the poison into the small intestine, where absorption will occur. The amount of toxin removed by gastric lavage is relatively small.

ASPHYXIATION

Suffocation, or **asphyxiation**, may occur at any age, but the incidence is greater in children. In suffocation, air does not reach the lungs and breathing stops. Common causes of suffocation are drowning, choking on a foreign substance inhaled into the trachea, and gas or smoke poisoning. The leading cause of preventable-injury death in infants younger than one year is mechanical suffocation (82%), which is most frequently attributed to soft bedding (69%), bedding overlays (blankets, persons; 19%), and wedging (entrapped between a mattress and a wall; 12%; Lambert et al., 2019). A young child may be strangled accidentally by the shoulder harness of a seat belt or become trapped while playing in a discarded refrigerator and suffocate.

Drowning is a form of suffocation. For children ages 1 to 14 years, fatal drowning is the second-leading cause of unintentional, injury-related death, second only to motor vehicle crashes (CDC, 2021b). Drowning is second only to birth defects for cause of death in children ages 1 to 4 years (CDC, 2019c). Most drowning deaths in young children occur because of inadequate adult supervision of a child in or near a bathtub or pool, even a small wading pool. Older children are more likely to drown while swimming or boating. Other factors include missing or ineffective fences around water, not wearing life jackets, drinking alcohol, and using drugs and prescription medication (CDC, 2021b). Disparity persists with the rates of drowning deaths between some racial and ethnic groups. Black children ages 5 to 9 years drown at 2.6 times the rate of White children, and Black children ages 10 to 14 years drown at 3.6 times the rates of White children. This number jumps to 7.6 times the rate of White children when considering death in swimming pools (CDC, 2021b).

Educating the public about the causes of suffocation can save many lives. Assessing the knowledge level of people, especially parents, is vital. Nurses need to be alert to hazards that might cause a child to asphyxiate or choke (see

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Box 27-1 on page 778). Unconsciousness, respiratory failure, and cardiac arrest can occur as a result of suffocation. Emergency measures must start without delay, beginning with the removal of any obstruction and administration of cardiopulmonary resuscitation (CPR). When teaching parents, the nurse should emphasize careful supervision of children and should outline specific situations that place children at risk for suffocation. Health education is a valuable preventive force (see Box 28-1, on page 841, for specific interventions).

Recall **Juanita Flores**, the mother of the child who fell off a cot. As part of the plan of care, review safe infant care with Juanita and provide anticipatory guidance related to toddler safety in preparation for the child's discharge home.

CHILD ABUSE

Protecting a child also includes being alert to manifestations that indicate *child maltreatment or abuse* (Box 28-2). In the United States in 2018, child protective services (CPS) agencies received an estimated 4.3 million referrals involving 7.8 million children, with approximately 67.3% of those reports coming from professionals (educators, legal/law enforcement, social services). Based on these reports, 3.5 million children were screened in, which means they received an investigation or an alternative response from the CPS agency. In 2018, 28.7% of the estimated 678,000 victims of maltreatment were younger than 3 years old. An estimated 1,770 children died of abuse and neglect, with 70.6% of child fatalities younger than 3 years old, and those younger than age 1 year accounting for almost half (46.6%) of total child fatalities (U.S. Department of Health and Human Services, Administration for Children and Families, Administration on Children, Youth and Families, Children's Bureau, 2020). Maltreatment includes physical (46.1%), sexual, or psychological abuse; includes sex trafficking; and may be a result of neglect, which is the most common form of maltreatment (72.8%). All 50 states have laws that require health care personnel to report suspected child abuse. To report abuse, contact The National Child Abuse Hotline at 1-800-422-4453 (1-800-4-A-Child).

Box 28-2 **Manifestations of Child Maltreatment**

The four common types of child abuse or maltreatment include:

Physical Abuse

Unexplained or repeated injuries resulting from physical force.

Manifestations include bruises, fractures (arms, legs, facial, ribs), burns, bite marks, head injuries, and any other indications of force.

Sexual Abuse

Engaging a child in sexual acts including fondling, rape, and exposing a child to other sexual activities.

Can be manifested by vaginal discharge, urinary tract infection, difficulty walking or sitting, sexually transmitted infections, and genital pain.

Emotional Abuse

Behaviors that harm a child's self-worth or emotional well-being.

Manifestations can include extremes in behavior, sleep problems, headaches or stomachaches, avoiding activities.

Neglect

Failure to meet a child's basic needs including housing, food, clothing, education, and access to medical care.

Source: Adapted from Fortson, B. L., Klevens, J., Merrick, M. T., Gilbert, L. K., & Alexander, S. P. (2016). Preventing child abuse and neglect: A technical package for policy, norm, and programmatic activities. National Center for Injury Prevention and Control, Centers for Disease Control and Prevention. https://www.cdc.gov/violenceprevention/pdf/CAN-Prevention-Technical-Package.pdf

School Age

ACCIDENTS

Although school-age children are increasingly independent, they still need help avoiding activities that are potentially dangerous. Accidents continue to be a leading cause of death. The nurse should counsel parents of school-age children about specific interventions for safety at home, at school, and in the neighborhood. All school-age children need to continue to be secured in safety seats, belt-positioning booster seats, or shoulder lap belts for their size. Use the Safety Belt Fit Test to determine when a child may safely use a seat belt without a booster (Box 28-3).

Each year, a significant number of children younger than 10 years are injured in *bicycle accidents*. Many of these injuries involve the head or face. The protective effect of bicycle helmets among children is well documented. Studies indicate that legislation and injury prevention strategies have had a positive impact on increasing helmet use and decreasing the number and severity of bicycle accidents that result in a head injury in this very vulnerable population. However, their use is far from universal. Because of their multiple experiences with children and parents, nurses—whether in the ED or a well-child setting—have many opportunities for health teaching related to bicycle safety and helmet use. Points to include in any teaching session include the following:

Box 28-3 Safety Belt Fit Test

Parents often ask, "When is it OK for a child to move from a booster seat to a seat belt?" If a child meets all of the following criteria, the child may sit in the back seat of a vehicle with a properly adjusted seat belt:

- Have the child sit in a back seat with their entire back and bottom against the vehicle's seat back. If the child's knees bend at the edge of the seat, go on with the test.
- Buckle the seat belt. If it stays low on the hips and is not resting on the soft part of the stomach, go on with the test.
- Check the shoulder belt. If it lays on the collarbone and shoulder, go on with the test.
- If the child is able to maintain the correct seating position with the shoulder belt on the shoulder and the lap belt low across the hips, then the child is ready to move from a booster seat to a seat belt.

If your child does not meet all four criteria, continue using a booster seat and retest again next month.

Source: Adapted from Safe Kids Worldwide. (2022). *Seat belt safety for big kids*. http://www.safekids.org/tip/seat-belt-safety-big-kids

- Children should wear helmets at all times when riding a bicycle.
- Young children who are secured in a child seat as a passenger on a bicycle should also wear a properly sized helmet.
- The helmet should rest flat on the top of the child's head (approximately 1 inch above the eyebrows) and fit snugly.
- The chinstrap on the helmet should be adjusted so that it fits securely. If you can slide two fingers under the strap, the helmet is too loose.
- Any helmet that is involved or damaged in a crash should be discarded and replaced.
- Parents are effective role models for their children when they also wear helmets while riding a bicycle.

Playground activity promotes the development of social skills, reduces anxiety, encourages creativity and independence, increases confidence and resilience, and has physical benefits (Bergeron et al., 2019). Strategies to reduce the risk and severity of playground injury to children, especially traumatic brain injury (TBI) in children ages 5 to 9 years, include attentive adult supervision, employing methods to reduce high-risk behavior, designing age-appropriate playground equipment, and creating an environment that is well designed and maintained (Cheng et al., 2016). Although the majority (56%) of playground-related injuries treated in EDs are fractures, contusions, and abrasions (CDC, 2019d), sport- or recreation-related activities (fall or interpersonal contact, roller sports, equestrian and related activities, skiing/snowboarding, water sports) can also result in TBI. TBI usually results from a blow, bump, or jolt to the head that causes disruption in brain function. The direct blow to the head causes the brain to accelerate into the skull and then return and bounce off the opposite side of the skull. The brain can also rotate inside the skull, resulting in further damage. Every year in the United States, over 500,000 children present to the ED with TBI, with more than 60,000 children requiring hospitalization (Yue et al., 2016). A *concussion* is a milder form of TBI that is usually sports related (CDC, 2020e). Nurses in a variety of settings need to be alert for indications of concussion. The common manifestations can be subtle, but parents, teachers, and nurses need to be aware of the following descriptions of symptoms by category that may require a 911 call and immediate ED attention:

- Physical: headache, vomiting, problems with balance, fatigue, dazed or stunned appearance
- Cognitive: mentally foggy, difficulty concentrating and remembering, confusion, forgets recent activities
- Emotional: irritability, nervousness, very emotional behavior, any change in personality
- Sleep: drowsiness, difficulty falling asleep, sleeping more or less than usual

Technology Alert

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

In an effort to minimize the risk of concussion and other TBIs, the Centers for Disease Control and Prevention (CDC) created the HEADS UP program. HEADS UP provides tools resources for parents, health care providers, and leaders/coaches associated with schools, school sports, and community youth sports. Check out the CDC website at: https://www.cdc.gov/headsup/index.html for useful videos, informational PDFs, mobile apps, graphics, podcasts, and social media links.

Evaluation immediately following a concussion includes assessment of airway, breathing, and circulation (ABCs) and any indication of a cervical spine injury. The Sport Concussion Assessment Tool (5th edition; SCAT5) is one of the more widely used tools; it is available in adult and child versions (Child SCAT5 for ages 5 to 12) and designed to be used by medical professionals (Davis et al., 2017; Echemendia et al, 2017). Treatment for an uncomplicated concussion includes monitoring, avoidance of medications (alcohol, sleeping tablets, aspirin, anti-inflammatories, narcotics), and physical and cognitive rest until a licensed practitioner medically clears the athlete to return to activity. Cognitive rest entails avoidance of any computer-based activity, reading, watching television, and playing games of any kind.

CHILD ABDUCTION

The possibility of child abduction also needs to be addressed with parents and children for this age group. Abduction occurs for a number of reasons and is a tragedy that devastates parents, families, and communities. Strangers, family members, friends, or neighbors may kidnap children. Some children suffer sexual assault or are murdered by their captors. Adults who prey on children often take advantage of the innocent and trusting nature of children to persuade the child to accompany them. Children, even the very young, need basic instructions on how to recognize and respond to a potentially dangerous situation. Health teaching should also emphasize the need for parents to be alert and vigilant at all times regarding the whereabouts of their children.

Teach parents and caregivers about the AMBER Alert System, which can be activated when a child is missing and believed to be kidnapped. This critical response program uses the resources of law enforcement and the media to notify the public about an abduction. As of January 1, 2013, any Wireless Emergency Alerts–activated phone is automatically enrolled to receive alerts regarding the President, any imminent threat, and AMBER Alerts (U.S. Department of Justice, Office of Justice Programs, n.d.). The AMBER Alert is a powerful tool that helps enlist the public to help recover kidnapped children and return them to their families.

BULLYING

According to the American Psychological Association (2020), an estimated 40% to 80% of school-age children experience bullying at some point and 10% to 15% may be either chronic victims or bullies themselves. **Bullying** is generally defined as a form of direct or indirect aggression that includes hostile physical, verbal, psychological, and/or relational behaviors. It is intentional, repeated over time, and commonly occurs in the context of a relationship, which means there is usually a power differential involved. Children who are bullied are different or perceived to be different by their peers for any number of reasons including economic status, religious affiliation, weight, minority or immigrant status, learning or behavioral issue, sexuality or sexual orientation, exposure to trauma, lack of close relationships or familial issues, and child maltreatment (Hornor, 2018). Bullying results in immediate harm and/or negative social, mental health, and physical health consequences for the victimized child.

Cyberbullying contains similar elements and is often seen in conjunction with in-person bullying. Cyberbullying involves using information and communication technologies to bully (text messages, chat rooms, photos, social media), which means it can be perpetrated from anywhere at any time, is pervasive, has the capacity for an unlimited audience, has the perceived veil of anonymity, and often involves severe privacy violations (Waasdorp & Mehari, 2019). Because of the methods used, cyberbullying can be more difficult to detect and address; the perception of anonymity makes the perpetrators bolder and decreases their ability to see the results of their actions and develop empathy.

Children who are bullied are at risk for developing physical health consequences, somatic issues (headaches, stomach aches, irritable bowel syndrome), school absenteeism, depression, anxiety, low self-esteem, eating and sleep disorders, substance use, delinquent behavior, academic failure, and suicidal ideation. Perpetrators of bullying may have similar issues, but often display less empathy and more conduct issues than their peers. The consequences of bullying often extend through adolescence and young adulthood, into middle age and beyond (Hornor, 2018).

Adolescent

DRIVING

Much of the adolescent's time is spent away from home with their peer group. Adolescents are particularly at risk for motor vehicle accidents because they spend so much time in automobiles and are prone to distracted driving and driving under the influence of substances. The CDC (2019g) lists motor vehicle accidents as the number one cause of death for adolescents. Teens ages 16 to 19 years are three times more likely to be in a fatal crash than drivers older than age 20 years, with the death rate for males in that age group twice as high as that of females. Graduated driver licensing systems facilitate adult supervision and limit high-risk situations by mandating a learner stage, an intermediate stage (limits on number/type of passengers and curfews), and an unrestricted stage that varies by state (Insurance Institute for Highway

Safety & Highway Loss Data Institute, 2020).

Distracted driving is a troubling trend for all age groups, but particularly for adolescents who comprise the largest percentage of distracted drivers. According to a report sponsored by the AAA Foundation for Traffic Safety (Carney et al., 2015), the most common forms of distraction for teens in the 6 seconds prior to a crash include: interacting with one or more passengers (15%), cell phone use (12%), looking at someone in the vehicle (10%), looking at something outside the window (9%), singing/dancing to music (8%), grooming (6%), and reaching for something (6%). According to a 2019 brief sponsored by the AAA Foundation for Traffic Safety (Arnold et al., 2019), distracted driving is underreported and on the rise. In their various roles, nurses have the potential to educate teenagers about this very dangerous risk to themselves and others by highlighting existing and emerging countermeasures. Education and/or behavioral countermeasures should focus on awareness campaigns, safe driving skills, the importance of wearing a seat belt, limited nighttime driving, obeying speed limits, never using a cell phone or texting while driving, and limiting the number of other teenagers in the car. Legislative countermeasures include handheld bans for all, texting bans for all, and complete cellphone bans for teens. Technology countermeasures that can be employed to assist teens include cellphone-blocking technology and driver monitor/feedback systems (Arnold et al., 2019).

SUBSTANCE USE, MISUSE, AND ABUSE

Alcohol use among teenagers is more common than use of tobacco or illicit drugs. Based on findings from a 2018 report (Substance Abuse and Mental Health Services Administration [SAMHSA], 2019), 9% of people ages 12 to 17 years currently use alcohol (2.2 million adolescents drank in the past month), 4.7% engage in binge alcohol drinking (five or more drinks on the same occasion at least once in the past month), and 0.5% drink heavily (five or more drinks more than 5 days in the past 30 days). By age 15 years, approximately 24.6% of teens have had at least one drink. People ages 12 to 20 years drink 4% of all alcohol consumed in the United States, with more than 90% of that alcohol consumed through binge drinking (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2021).

Nurses and parents should collaborate to reinforce safety behaviors in adolescents. Enforcement of zero tolerance laws regarding drinking age and driving while under the influence of alcohol, prevention programs in schools, and family efforts to influence whether their children consume alcohol are all significant factors aimed at preventing underage drinking. Successful approaches are comprehensive and consider social and environmental factors, genetics, personality, rate of maturation and development, and level of risk (NIAAA, 2021).

Illicit drug use increased among adolescents (ages 12 to 17 years) the past three reporting cycles: 2016 (15.8%), 2017 (16.3%), and 2018 (16.7%). An average of 4.2 million adolescents used illicit drugs in 2018 (SAMHSA, 2019). Teenagers abuse legally available drugs such as prescription medications (pain relievers, tranquilizers, stimulants, and sedatives) and over-the-counter (OTC) cough, cold, sleep, and diet medications. They also use illegal substances such as marijuana, cocaine, heroin, inhalants, and hallucinogens such as LSD. *Designer drugs*, synthetic/chemical derivatives of known illegal drugs, have seen a resurgence in the past 10 years. These total unregulated and typically legal designer drugs have a high potential for abuse and make their way onto the market under the guise of harmless names (Foundation for a Drug-Free World, 2020). The most popular synthetic and designer drugs include:

- MDMA: *Ecstasy*, *Molly, X, Hug Drug, Lover's Speed, Peace*; stimulant (euphoria) and mild hallucinogen/psychedelic (U.S. Department of Justice: Drug Enforcement Administration, 2020)
- Fentanyl analogues (acetyl fentanyl, carfentanil, valeryl fentanyl, fluoroisobutyryl fentanyl: *Apache*, *China Girl*, *China White*, *Dance Fever*, *Friend*, *Goodfellas*, *Jackpot*, *Murder 8*, *Tango & Cash*; synthetic opioid most commonly involved drug in overdose deaths) (National Forensic Laboratory Information System, 2021; National Institute on Drug Abuse, 2019a)
- 2C-B: psychedelic/psychostimulant (Papaseit et al., 2018); popular on the dark web
- NBOMe: *N-bomb*, *N-boom*, *Dots*, *251-NBOMe*; hallucinogen (Zawilska et al., 2020)
- Desomorphine: *Krokodil*, *Crocodil*, *Crocodile*, *Russian Magic*, *Poor Man's Heroin*, *Zombie Drug*; highly addictive opioid derivative of codeine with narcotic and analgesic effects that is more common internationally (U.S. Department of Justice: Drug Enforcement Administration, 2019)
- Bath salts: *Bliss, Blue Silk, Cloud Nine, Drone, Energy-1, Ivory Wave, Lunar Wave, Meow Meow, Ocean Burst, Pure Ivory, Purple Wave, Red Dove, Snow Leopard, Stardust, Vanilla Sky, White Dove, White Knight, White Lightning*; stimulant (U.S. Department of Justice: Drug Enforcement Administration, 2020)
- Synthetic cannabinoids (THC): *Spice, K2, Blaze, RedX Dawn, Paradise, Demon, Black Magic, Spike, Mr. Nice Guy, Ninja, Zohai, Dream, Genie, Sence, Smoke, Skunk, Serenity, Yucatan, Fire, Crazy Clown*; psychoactive (U.S. Department of Justice: Drug Enforcement Administration, 2020)

Warning signs of alcohol and drug abuse during adolescence include physical fatigue, personality change, poor judgment, sudden mood changes, withdrawal from the family, a variety of school-related issues (negative attitude, drop in grades, failure), and social problems. Parents need to focus on open communication with their teenagers, role model appropriate behavior, and seek help and guidance once a problem with alcohol or drug use is recognized.

Cigarette smoking in adolescents (ages 12 to 17 years) in 2002 was at 13%. This percentage has declined every year since then and is currently at an all-time low of 2.7% (SAMHSA, 2019). However, e-cigarette use, also called *vaping*, with flavored nicotine, nicotine, and marijuana continues to rise in this population (CDC, 2020c). In 2018, 27.1% of

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

high school students and 7.2% of middle school students reported current tobacco use, most commonly via e-cigarettes. Federal law mandates a minimum age of 18 years to purchase tobacco products and bans billboard advertising within 1,000 ft of schools and playgrounds. However, campaigns for e-cigarettes and the flavoring that was banned in refillable devices but not disposable ones (U.S. Food and Drug Administration, 2020), tends to appeal to teens. Teenagers and younger children may be influenced to use tobacco products by the Internet, music, television, and movies, but parents can be the greatest influence. Conversations regarding the risks of smoking should begin as early as ages 5 to 6 years because many children start using tobacco products at age 11 years and may be addicted by age 14 years (American Cancer Society [ACS], 2019).

PIERCINGS AND TATTOOS

Body piercing has become increasingly popular with adolescents and young adults. Common sites for piercing include the ears, nose, eyebrows, lips, tongue, nipples, navel, and genitals. If not performed in a professional, clean environment, there is a risk for contracting hepatitis B or C, tetanus, or HIV. Even in a sterile environment, some common risks of piercing include chronic infection, skin allergies, abscess formation, inflammation, nerve damage, or prolonged bleeding (Gardner, 2019).

Although the U.S. Food and Drug Administration (FDA) has opted not to control piercings, it has provided some safety and regulatory guidance for *tattoos*, which have become increasingly popular (2019). Tattoos are permanent markings on skin surfaces viewed as a form of body art. Risks involved in tattooing include infection (similar to piercings), allergic reactions, granulomas (nodules), keloid formation (scarring), complications with MRIs, dissatisfaction, and problems associated with removal (FDA, 2019b). Although still regulated at the state (not federal) level, the FDA continues to collect data on pigments used in tattoo inks that are not approved for skin contact. Teens and their parents, who may be required to issue consent, need to be careful with both permanent and temporary tattoos. In particular, the FDA issued a warning statement about black and blue henna tattoos and other inks that also contain only hair dye. Meticulous post-piercing and tattoo care reduce the risk for developing an infection. Nurses need to be informed about the health risks in order to be effective and well-informed health educators.

FIREARMS

There are significant security issues related to adolescents and the use of guns. International studies indicate that when considering all high-income countries, 91% of firearm deaths of children ages 0 to 14 years occur in the United States. Nearly 1,300 children (ages 0 to 17 years) in the United States die from gunshot wounds, and 5,790 children are treated for gunshot wounds each year. Boys (82% to 84%), adolescents (ages 13 to 17 years), and minorities are more likely to be affected. In all cases, a handgun is the most common firearm used. Younger children are more likely to be involved in multivictim events or in family disputes and killed in a home (85%). Older children are more likely to die in the context of crime and violence (self-directed 38%, homicides 53%, or unintentional 6%) and have approximately the same likelihood of being killed in a home (39%) as on the streets (38%). Firearm-related deaths are the second-leading cause of injury-related death in children (ages 1 to 17 years), second only to motor vehicle accidents, and the third leading cause of death in children overall (Fowler et al., 2017). Adolescents need encouragement and education about ways to solve arguments without guns and violence, and guidance and direction for developing resources to cope with the stresses of daily living. Strategies to minimize firearm injuries should consider more global violence prevention strategies, poverty, social relationships, the environment, and other contextual factors related to social determinants of heath that contribute to a culture of violence.

Think back to **Kara Greenwood**, the adolescent who is to present a discussion on adolescent dangers. Numerous issues face adolescents today; providing safety information is crucial to help adolescents make mature decisions about health hazards they are likely to encounter.

INTERNET AND SOCIAL MEDIA

The use of the Internet has grown, particularly among teenagers. This has prompted legitimate safety concerns by parents/caregivers. Certain people take advantage of the vulnerability of young children, teenagers, and adults with intellectual disabilities by stalking them online and exploiting them sexually and financially (Buijs et al., 2017). Meeting

someone with whom the person has communicated online poses the greatest safety risk for children. Since online and offline safety risks are very similar, educational programs should focus on the integration of online dangers into long-standing efficacious programs that address things such as offline bullying, dating abuse, and sexual abuse/predators (Finkelhor et al., 2020). Safety guidelines for parents include addressing the following with their children:

- Remind adolescents that anything posted on the Internet is available to the public at large in perpetuity and can resurface at any time. Posts or tweets made today may impact on their ability to secure a job in the future.
- Keep identifying information private (e.g., full name, address, telephone number). Use a screen name that does not contain any identifying information.
- Investigate filtering software or methods of blocking out objectionable information.
- Ask for access to phone, social media accounts, and email, and maintain friend-status on your teen's Facebook, Instagram, Snapchat, and other online accounts.
- Ask teens to avoid public chat rooms and forums where they do not have a personal contact. Computer sex offenders often use chat rooms to contact potential victims.
- Never allow a child to arrange a meeting alone with someone the child has met online.
- Never respond to e-mails or messages that are suggestive, obscene, threatening, or inappropriate in any way. Be alert for downloaded files with suffixes that indicate images or pictures (e.g., .jpg, .gif, .bmp, .tif, or .pcx). If a parent/caregiver becomes aware of the transmission or viewing of child pornography while online, the adult should report this immediately to the local FBI office and the CyberTipline at the National Center for Missing and Exploited Children (1-800-843-5678).
- Emphasize that a good amount of what is said or written online may not be true. Teach tips for evaluating sites and promote online literacy.
- Monitor and set rules regarding the amount of time that adolescents spend on the computer or with their other devices (tablets, cell phones).
- Respect your teen's privacy as possible. Recognize that the Internet provides them the ability to socialize and connect with people—allow them space and provide them the tools they need to maintain their personal safety.

SEX TRAFFICKING

An amendment to the Justice for Victims of Trafficking Act of 2015 includes the need for identification, assessment, and reporting of suspected sex trafficking for anyone younger than age 24 years. Victims of sex trafficking may be younger than age 3 years (1%), but the percentages increase for older victims, with 71.9% of victims ages 14 to 17 years. The majority of the victims of sex trafficking are one of three races: White (41.6%), Black (23.5%), and Hispanic (19.3%), which is similar to the distribution for other maltreatment types. Although 16.1% of perpetrators are parents and 34.5% are known to be non-parents, more than half (54.3%) of the victims of sex trafficking have an unknown/missing relationship to their trafficker (U.S. Department of Health and Human Services, Administration for Children and Families, Administration on Children, Youth and Families, Children's Bureau, 2020). Although sex trafficking affects teens disproportionally, this is a public health issue that requires community engagement and monitoring, especially in communities where trafficking is more prevalent.

Adult

DRUG USE AND POISONING

Drug use trends among college-age adults (ages 19 to 22 years) has changed significantly over the past few years. Marijuana use is at an all-time 35-year high for college students and their non-college counterparts (43%), with daily/near daily use approximately twice as high among the non-college group. Nicotine vaping increased dramatically between 2017 and 2018, with numbers topping 15.5% for the college students and 12.5% for non-college students. Opioid misuse and binge drinking declined significantly in this age group. Adderall® misuse is higher among college students in general but varies in that college men and non-college women had higher rates than their counterparts (National Institute on Drug Abuse, 2019b).

In 2018, there were 67, 367 drug poisoning (overdose) deaths in the United States, which is a 4.1% drop from 2017. Causes were classified as unintentional (87.4%), suicides (7.2%), undetermined intent (5.2%) or homicides (less than 1%). Types of drugs involved included heroin, opioids (natural, synthetic, and semisynthetic), methadone, cocaine, psychostimulants with abuse potential, and combinations of these drugs. Increases in deaths attributed to drugs such a fentanyl or their analogs, cocaine, and psychostimulants were noted in 2018 (Hedegaard et al., 2020).

INTIMATE PARTNER VIOLENCE

Intimate partner violence (IPV) involves: physical violence (hitting kicking, or other physical force), sexual violence (forcing a sex act, sexual touching, or a nonphysical event without consent), stalking (a pattern of repeated, unwanted attention and contact) and/or psychological aggression (verbal and nonverbal communication intended to mentally or emotionally harm and/or exert control by a current or former intimate partner, such as a spouse, dating partner, or sexual partner). It is not uncommon for several types of IPV to occur in tandem (CDC, 2019e). For about 11 million women and 5 million men, IPV began in adolescence and is referred to as teen dating violence (TDV). In the United States,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

36.4% of women experienced sexual violence, physical violence, and/or stalking by an intimate partner during their lifetime, with 25.1% of women reporting some residual IPV-related impact. More than one third (36.4%) of women experienced psychological aggression by an intimate partner during their lifetime. Men are also affected by IPV with 33.6% of men experiencing sexual violence, physical violence, and/or stalking; 34.2% experienced psychological aggression by an intimate partner during their lifetime (Smith et al., 2018).

Vulnerable Population Alert

Intimate partner violence (IPV) most frequently occurs before age 25 years; many men and women first encounter IPV before age 18 years. This is a public health problem that requires a multifaceted approach to primary prevention and early intervention. The CDC has published technical packages that outline the *strategy*, the *approach*, and the *evidence* to prevent or reduce public health problems. Check out the violence prevention packages at https://www.cdc.gov/violenceprevention/pub/technical-packages.html.

The nurse is often the initial health care provider in contact with a victim of IPV or child abuse. Prompt recognition of the potential or actual threat to safety is crucial, and the nursing assessment may play a vital role in identifying a harmful environment. It is not always easy to confirm that a person has sustained injuries as a result of IPV. Many victims of IPV are reluctant to admit any abuse and may even deny that it has occurred. In fact, few victims of IPV ever seek help from the legal or health care systems (Breiding et al., 2015). Some studies have suggested that routine screening is effective, but most experts agree that asking simple, specific questions in a private setting (even the restroom, if the perpetrator is present) can also be helpful. Box 28-4 is an example of an assessment tool that the nurse can use to identify victims of IPV.

There are special clinical considerations for IPV in LGBTQ relationships. Although most aspects of IPV are similar to those identified in heterosexual and/or cisgender relationships, one aspect that is unique is the power inherent in *outing* a survivor's sexual or gender identity that may be used as a wedge to isolate the victim from family and other support system. Baseline discrimination based on sexual orientation or gender identity is compounded for those from racial/ethnic minority groups and those who are socioeconomically disadvantaged. Fears of the LGBTQ IPV survivor include fear of generating further negativity toward the LGBTQ community, fear of rejection from family members or friends who do not accept the underlying relationship, fear of the impact on their identity or future LGBTQ relationships, and fear of engaging with health care professionals or institutions who do not accept LGBTQ relationships (American Psychiatric Association, 2019). Assessment methods for identification of perpetrators and victims of IPV "should focus not on the sex, gender identity, or gender expression of the person but instead focus on a thorough assessment of empathy, agency, and entitlement" (American Psychiatric Association, 2019, p. 3). At least 49% of transgender and gender nonconforming people killed in 2019 were killed by someone known to the victim, or a friend, family member, or intimate partner. Young transgender women of color who live in the South are disproportionately affected (Human Rights Campaign Foundation, 2019). This provides an excellent example of **intersectionality**, where race, sex, gender, class, and other individual characteristics intersect and overlap with one another, often leading to an increased burden of discrimination on several fronts and other negative outcomes (Crenshaw, 1989). As with all cases of IPV, providers must work to understand the relationship as a whole and consider patterns that indicate a power differential, controlling behaviors, expressions of fear, decision-making dominance, and/or barriers to social engagement.

Nurses may assist in outlining the components of a safety plan (The National Domestic Violence Hotline, n.d.). IPV is a complex issue and simply leaving may not be an immediately viable option. Safety plans can include information on the following:

- Safety while living with an abusive partner: remove weapons, keep phone accessible, develop a signal to notify trusted friends and family, teach your children how to get help and how to get out safely, keep the car keys accessible and the car full of gas, minimize online footprint that can be used for location purposes, do not wear jewelry or scarves that could pose a threat to your safety, keep copies of important documents, create a *go-bag* with copies of important documents, medications, and other essentials.

Box 28-4 **E-HITS Intimate Partner Violence Screening Instrument**

Extended–Hurt, Insulted, Threaten, Scream	Over the last 12 months, how often did your partner: 1. Physically hurt you? 2. Insult your or talk down to you? 3. Threaten you with harm? 4. Scream or curse at you? 5. Force you to have sexual activities?	Each item is answered on a 5-point Likert scale: • 1 = never • 2 = rarely • 3 =

sometimes
- 4 = fairly often
- 5 = frequently

Score range: 5–25
Cutoff for IPV: ≥7

Source: Iverson, K. M., King, M. W., Gerber, M. R., Resick, P. A., Kimerling, R., Street, A. E., & Vogt, D. (2015). Accuracy of an intimate partner violence screening tool for female VHA patients: a replication and extension. *J Trauma Stress*, *28*(1), 79–82. https://doi.org/10.1002/jts.21985

- Safety planning with children: teach them how to call 911, teach them not to intervene, involve them in the plans for physical safety, teach them IPV is not their fault.
- Safety planning for pets: stock extra supplies, copy their medical records.
- Safety planning during pregnancy: recognize the heightened risk, utilize time with your provider to discuss IPV issues, take a female-only prenatal class.
- Emotional safety planning: seek out supportive people, identify and work toward goals, create a peaceful space in your environment for yourself, value yourself, remember you deserve to be kind to yourself.
- Leaving a relationship: keep evidence of abuse, plan with your children, use identified community resources, grab your go-bag, communicate your history and needs to new support systems, protect yourself and avoid the perpetrator after leaving, and consider your legal options.

Nurses must follow any policies or procedures outlined by their facility and document any interactions with victims of IPV. Many institutions have a trained victim advocate available. The nurse must keep in mind that regardless of the outcome, the victim of IPV has the right to self-determination without judgment—they often know what is best and their agency should be respected. Additional resources include the National Domestic Violence Hotline (1-800-799-SAFE), which will provide contact information regarding local domestic violence shelters and other resources, including those networks that are LGBTQ-focused.

Older Adult

FALLS

Although one of every four older people (age >65 years) falls each year, fewer than half of them tell their provider (CDC, 2017). Many falls at home go unreported because they do not cause injuries requiring medical attention. However, injuries from falls may also go unreported because older adults fear activity restrictions, loss of independence, or placement in a long-term care facility. The fear of falling can also cause anxiety and panic, which may make an older adult more vulnerable to a fall. One out of five falls causes a serious injury such as broken bones or a head injury. Interestingly, more than 95% of hip fractures are caused by falling, usually sideways from a ground-level fall. At least 300,000 older adults are hospitalized for hip fracture every year. This means that, when adjusted for inflation, the direct medical costs for fall injuries are $50 billion annually, with Medicare and Medicaid covering 75% of these costs (CDC, 2021a).

Assessment of the risk for falling includes the use of nursing history and physical examination. Ask about any previous falls—evidence shows that self-reported history of falls is a significant predictor of future falls and risk of fracture (Soh et al., 2020). Note any assistive devices that the patient uses (e.g., a cane or walker). Be alert to any history of drug or alcohol use disorder. Consider comorbidities such as obesity, osteoarthritis, diabetes, hypertension, chronic pain, depression, and any associated medications (Noohu et al., 2017). Characteristics of older adults most strongly associated with fall risk are depression, difficulty completing routine errands, and difficulty with ADLs (bathing or bathing); injuries from a fall are most strongly associated with depression, difficulty with ADLs, and single/unmarried status (Bergen et al., 2019). Family members and significant others are often valuable resources. Knowledge of family support systems and the home environment is crucial for the nurse to plan protective health measures. Since the mid-1980s, a fall is generally categorized as either an *accidental fall* (fall of otherwise low-risk adults; clutter or a spill cause a person to trip), an *anticipated physiologic fall* (a direct consequence of gait imbalances, effects of medication, or dementia), or an *unanticipated physiologic fall* (caused by unknown or unexpected medical issues such as a stroke or seizure; Morse et al., 1987). An initiative from the CDC, STEADI (Stopping Elderly Accidents, Deaths & Injuries; CDC, 2019b) provides an excellent algorithm for health care provider fall risk screening, assessment, and intervention (Table 28-1 on page 850 and Fig. 28-1 on page 850).

Major causes of falls in the home include slippery surfaces, poor lighting, clutter, and improperly fitting clothing or slippers. Common traffic pathways in the home, the bathroom, and access areas to and from the home are hazardous areas for older adults. Measures as simple as installing handrails in bathrooms and on stairs, ensuring good lighting, and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

discarding or repairing broken equipment around the home help prevent accidents (see Box 28-1, page 841). Assessments by the nurse can play a vital role in promoting safety in the home.

Consider **Bessie Washington**, the older woman who ambulates with a walker after suffering a stroke. A thorough home safety assessment by the home care nurse is essential when developing the patient's plan of care. This assessment would be valuable in identifying areas that promote patient safety and hazards that need to be addressed.

Evidence supports the positive role that calcium supplementation and vitamin D play in promoting skeletal health and reducing fall risk for this population (CDC, 2019b). Regular exercise has a positive effect on bone and muscle strength, balance, and flexibility of joints. Exercise, particularly regimens including stability-challenging exercises, has been proven to reduce the number of falls by 32% and the number of people who fall by 22% (Hamed et al., 2018).

MOTOR VEHICLE ACCIDENTS

Most accidents that involve older adults are preventable. Although older adults tend to wear safety belts, observe speed limits, drive fewer miles, and abstain from drinking while driving, due to age-related vulnerabilities, medical conditions, and prolonged recovery risks, seniors have the highest crash death rate after adolescents (AAA, 2022). Vision changes, slowed reaction time, alterations in judgment, and decreased range of motion affect the older driver. Some become overly cautious, whereas others are prone to careless behavior. Teach the following interventions to help older adults drive safely: maintain the automobile in optimal driving condition, schedule regular eye examinations, wear corrective lenses when necessary, drive less after dark, avoid driving in bad weather, avoid difficult roads during peak traffic times, and keep noise from the radio and other equipment to a minimum. Some states require additional testing for older adults before they can renew their driver's license.

Table 28-1 Fall Risk Factors

MODIFIABLE	
• Poor gait and balance • Strength issues • Visual impairment • Problems with feet and/or shoes • Comorbidities documented (depression, osteoporosis)	• Use of medications that increase falls risk • Orthostatic hypotension • Hazards in the home (and community) • Vitamin D deficiency
Start by addressing these modifiable issues that can be either intrinsic or extrinsic	
INTRINSIC (PERSON-BASED)	**EXTRINSIC (ENVIRONMENT-BASED)**
Advanced age	Lack of stair handrails
Previous falls	Poor stair design
Muscle weakness	Lack of bathroom grab bars
Gait and balance problems	Dim lighting or glare
Poor vision	Obstacles and tripping hazards
Postural hypotension	Slippery or uneven surfaces
Comorbidities and vitamin D deficiencies	Medications
Fear of falling	Improper use of assistive devices (canes, walkers)

Source: Adapted Centers for Disease Control and Prevention (CDC). (2019b). *Resource algorithm for fall risk*

screening, assessment, and intervention. https://www.cdc.gov/steadi/pdf/STEADI-Algorithm-508.pdf

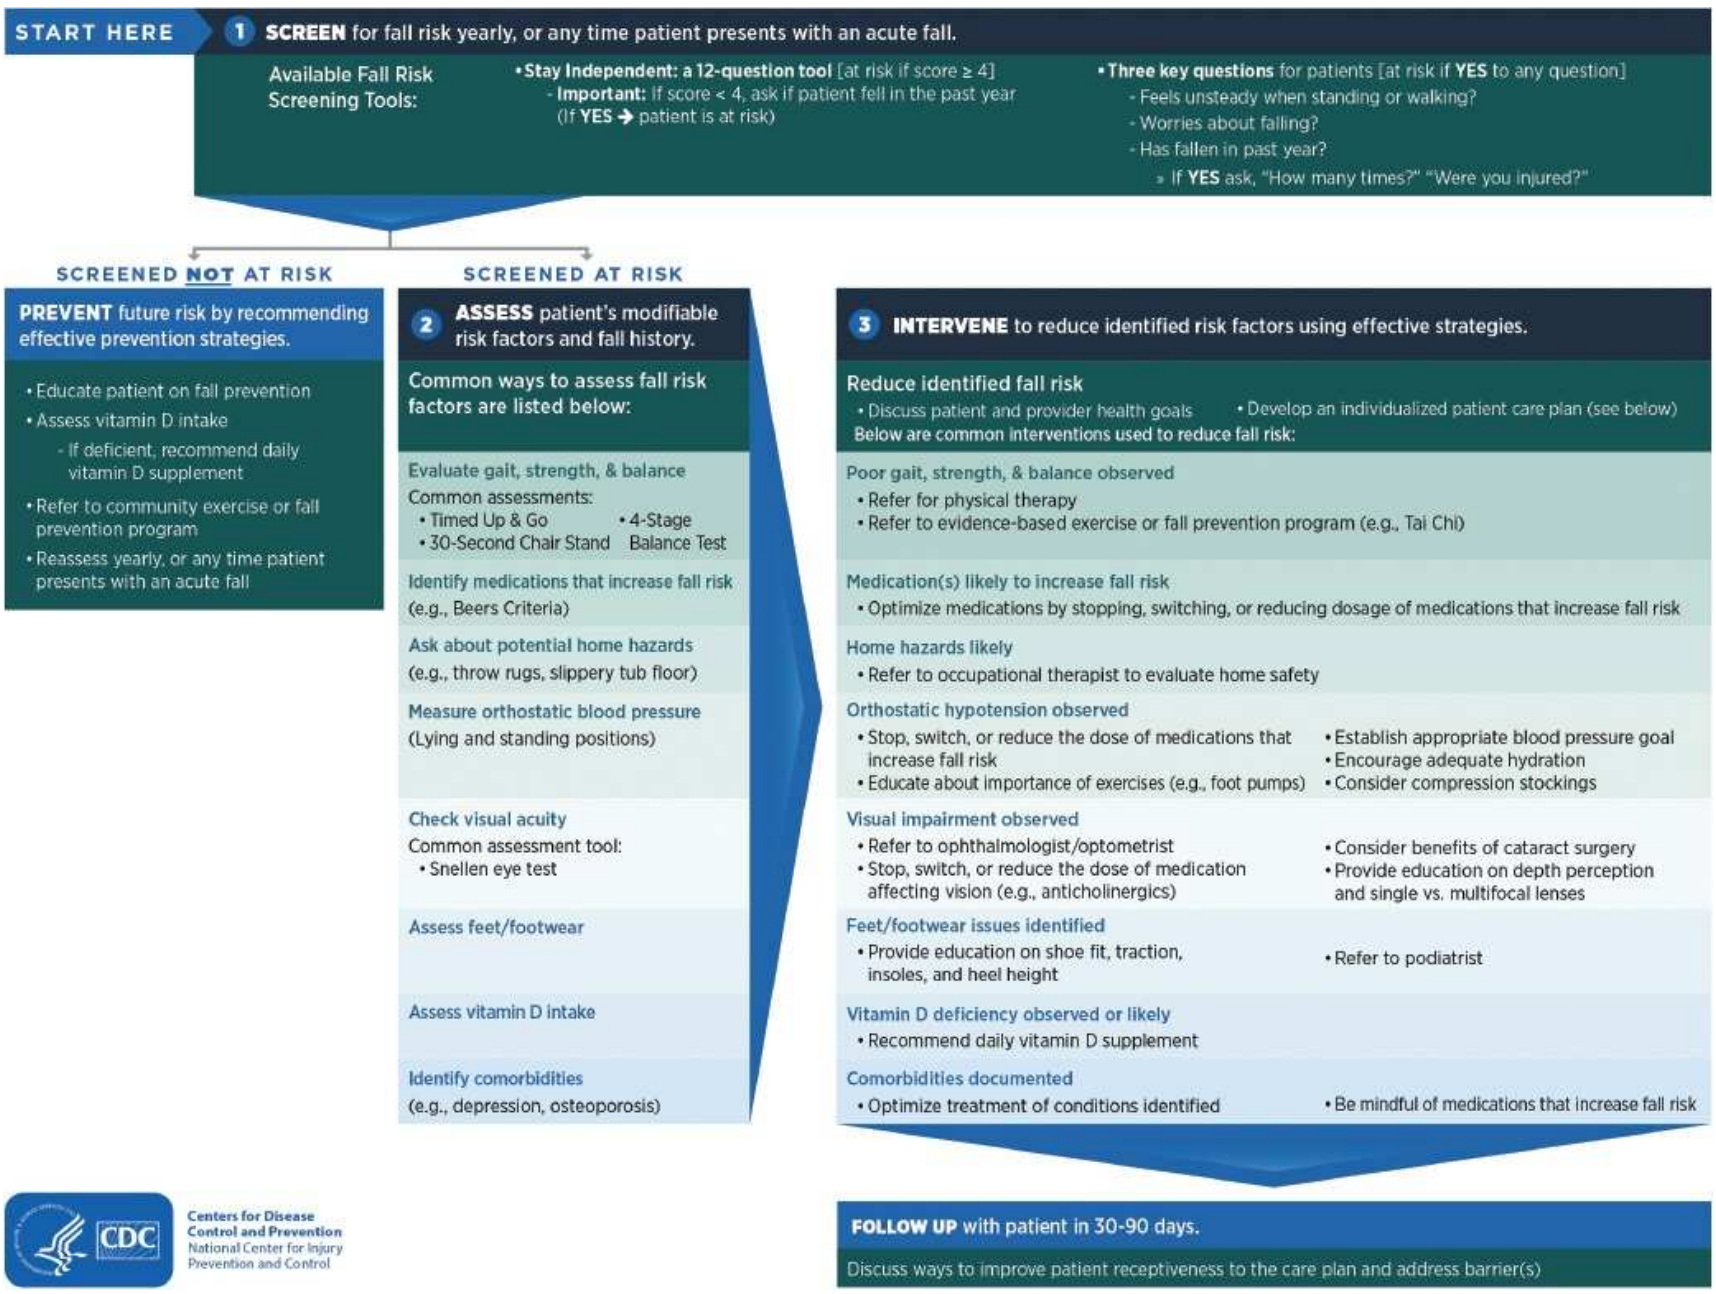

FIGURE 28-1. Algorithm for Fall Risk Assessment and Interventions. (*Source:* From the Centers for Disease Control and Prevention [CDC, 2019b] and Stopping Elderly Accidents, Deaths & Injuries [STEADI]. https://www.cdc.gov/steadi/pdf/STEADI-Algorithm-508.pdf)

Focus on the Older Adult

TEACHING TIPS TO PREVENT MEDICATION-RELATED POISONING

Age-Related Changes	Nursing Strategies
Confusion	• Do not hesitate to call the provider, nurse, or pharmacist with any questions. • Develop good communication with your provider, nurse, and pharmacist. • Use a medication calendar or diary to keep track of your dosing schedule. • Use a pill dispenser or pre-filled medication packs as a reminder tool.
Reduced vision	• Request large-print labels from your pharmacist.
Polypharmacy	• Report side effects from medications to your health care provider. • Do not share medications with others or take their pills. • When a drug is discontinued, discard any remaining medication appropriately. • Fill all your prescriptions at one pharmacy.
Effect of drugs in the aging body	• Keep the telephone numbers for your health care providers and the PCC in a readily accessible place. • Do not stop taking any prescription drug or change the dose without first consulting the provider or nurse. • Avoid doubling a dose if you forget a medication. Check with the health care provider or nurse first. • Avoid mixing alcohol with medicines without first checking with

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

the pharmacist.

FIRE

Fires also are a significant hazard for older adults, representing 40% of all fire deaths, with 2.7 times (age >65 years) and 3.8 times (age >85 years) greater risk of dying in a fire than the total population (U.S. Fire Administration, 2020). Factors such as confusion, forgetfulness, and diminished visual and olfactory senses place them at greater risk for burn injuries. Health teaching should include additional safety precautions if the older adult smokes in the home. Because it may be difficult to distinguish the intensity of temperatures, heating devices often used by older adults need to be carefully monitored and regulated. Smoke detectors indicate the presence of a fire that may not be recognized by an older adult with a diminished sense of smell.

POLYPHARMACY AND POISONING

Accidental overdosing on medications is also a safety risk, possibly related to poor eyesight or confusion. Special devices such as medication trays or electronic dispensing systems can be prefilled to help prevent older adults from taking additional doses (see Remote Medication Monitoring System in Chapter 30 on p. 940).

Nursing education efforts can also change behaviors that place older adults at risk for medication-related poisoning. Although poisonings happen more frequently in children, providers receive many calls from adults, particularly older adults, regarding accidental poisonings. Suggestions for preventing poisoning in older adults are included in the accompanying box, Focus on the Older Adult.

ELDER ABUSE

Elder abuse has no universally accepted definition, but legal, professional, and governmental definitions include elements of physical, sexual, and/or psychological abuse, neglect (including abandonment), and/or financial exploitation. The perpetrator is generally known and trusted by the vulnerable elder, the perpetrator's actions are intentional, and the end-result is a serious risk of harm to an older adult (U.S. Department of Health and Human Services, Administration for Community Living, n.d.; See Chapter 23 for a more complete description of the types of elder abuse.) Given the expanding number of people older than age 65 years, the incidence of maltreatment in this vulnerable population is expected to escalate. In most of the reported cases, a family member is the one who abused the older adult. Disability, dementia, and place of residence (private home or community setting) all impact the type, duration, and residual physical, psychological, financial, social, and other effects of elder abuse (U.S. Department of Health and Human Services, Administration for Community Living, n.d.). Nurses must be alert to any indications of elder abuse, document any injuries or behaviors that suggest elder abuse, and report suspected incidents to appropriate facilities in states where it is required. It is important to observe and objectively document voice tone, interactions, and personal touch between the older adult and a caregiver. If abuse is suspected, speak to the older adult in a private setting away from the caregiver, and work with the interprofessional team to coordinate expertise, resources, and interventions. Follow all guidelines and protocols regarding reporting and best practices (U.S. Department of Health and Human Services, Administration for Community Living, n.d.). When possible, addressing caregiver stress and caregiver substance abuse issues may help to prevent elder abuse.

Patient Environments

Certain work, social, and home environments inherently place people in more hazardous situations. Habits and routines fostered by the environment also directly impact safety risks. For example, following the law and wearing a seatbelt, if taught from a young age, becomes second nature. Do not forget to consider developmental issues discussed earlier in this chapter within the context of environment. For example, young and middle-aged adults need to be reminded about the effects of stress on their lifestyle and health. Coping with the demands of raising a family and succeeding in a career may lead to unsafe health habits and an often socially acceptable use of drugs or alcohol.

Work Environment

Occupation and work environment often affect a person's safety. People who work in certain occupations may experience exposure to health hazards, such as excessive noise, pollution, toxic chemicals or vapors, or infectious agents. For example, a worker who operates industrial machinery or works with chemicals has a greater risk for accidental injury. Exposure to excessive noise (e.g., a construction site, extremely loud music) may lead to hearing loss. Health care staff who suffer sleep deprivation due to extended work hours and variable shift assignments are more likely to commit errors and be a factor in adverse events (see further discussion in Chapter 34). Nurses working in the operating room are regularly exposed to surgical smoke, a byproduct of laser and electrocautery procedures. Surgical smoke contains chemicals that cause upper respiratory tract irritation and inflammation.

Self-Care Alert

Nurses working the operating room who are exposed to surgical smoke must complete competency validation, participate in ongoing education and training, and engage in the review of policies and procedures to promote the health and well-being of themselves and the entire surgical team.

Operating room personnel must be empowered to use smoke-evacuation practices (Association of periOperative Registered Nurses [AORN], 2020). Reproductive hazards may exist for females with long-term exposure to certain anesthetic agents. Certain drugs can also pose risks to health care professionals, but regulations and standards exist to protect health care personnel. For example, General Chapter <800> outlines a standard generated by the U.S. Pharmacopeial (USP) Convention (2019) that describes quality and practice standards for health care personnel, including nurses, who handle hazardous drugs. Nurses remain at increased risk for musculoskeletal (back) injuries, needlestick and sharp injuries, exposure to hazardous and toxic chemicals, radiation exposure, exposure to infectious diseases, stress that includes moral distress, and workplace violence. Workplace violence, consisting of both physical and psychological damage, has been identified as a major issue for health care providers (American Nurses Association, 2019). The Joint Commission has issued a sentinel event alert on workplace violence that specifically addresses the prevention of physical and verbal violence, and promotes reporting of violence in the health care setting (The Joint Commission, 2018).

Nurses need to adhere to standards, guidelines, recommendations, and policies to promote safety and minimize preventable injury.

Social Environment

Some people by nature are more inclined to take risks and jeopardize their safety. For example, some people do not use appropriate protective equipment, such as wearing a helmet when riding a motorcycle or bicycle. Such behaviors, whether voluntary (refusal) or involuntary (cannot afford) increase the risk for injury.

Stress may precipitate an unhealthy lifestyle that involves drug or alcohol abuse. For example, a high school student involved in multiple school activities and intent on maintaining excellent grades may turn to an addictive substance such as methamphetamine as a stimulant. This drug temporarily allows the student to remain alert for more hours each day and complete required class assignments but has significant negative consequences. See the PICOT in Practice box for more information.

Vulnerable populations also need support and attention, regardless of the circumstances that made them vulnerable. Social determinants of health include aspects of social and physical environments that involve key issues related to economic stability, neighborhood and built environment, social and community context, health and health care, and education (see Chapter 3, p. 56). A person's sense of security and well-being are directly tied to conditions in the environment where they reside. Addressing the health disparities and inequities in an environment, particularly those at the system or institutional level (e.g., racism or discrimination against LGBTQIA+ persons), requires a change in practice, policies, research, and community partnerships that will directly affect health outcomes, as well as public safety, social isolation, education, violence, and unequal access to resources (CDC, 2019h; U.S. Department of Health and Human Services, Office of Disease Prevention and Health Promotion, 2020a). Nurses have always been strong patient advocates regarding safety concerns for vulnerable populations. See Nursing Advocacy in Action for an example of a nurse supporting a vulnerable patient's safety and health.

Home Environment

Environmental safety hazards can result in poisoning and fires. Nursing assessment includes identifying people at risk and recognizing unsafe situations that involve both physical and interpersonal dangers (see discussions of abuse and IPV earlier in this chapter). Recognizing these factors helps the nurse develop an individualized plan of care and nursing interventions for protecting the patient in the home.

PICOT in Practice

ASKING CLINICAL QUESTIONS

Scenario: You are a public health nurse working for the local Health Department. As part of a national smoking cessation initiative, you are planning a presentation on different options to help those who want to quit smoking. Previous presentations have concentrated on nicotine replacement therapies (NRTs) and/or counseling to assist those interested in smoking cessation. You wonder if electronic cigarettes (e-cigarettes) that typically contain nicotine, have any role in helping people stop smoking.

E-cigarettes have become popular, especially with younger smokers, and you wonder if you could leverage this popularity and use e-cigarettes (with nicotine) in place of other NRTs. You decide to research the topic further to see if the use of e-cigarettes (with nicotine) can help an individual quit smoking.

- **Population:** Smokers who wish to quit
- **Intervention:** Use of electronic cigarettes

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- **Comparison:** Nicotine replacement therapy
- **Outcome:** Smoking cessation
- **Time:** 12 months

PICOT Question: In smokers who wish to quit, does the use of e-cigarettes (with nicotine) compared to NRTs help achieve smoking cessation in a 12-month period?

Findings:

1. Hartmann-Boyce, J., McRobbie, H., Lindson, N., Bullen, C., Begh, R., Theodoulou, A., Notley, C., Rigotti, N. A., Turner, T., Butler, A. R., & Hajek, P. (2020). Electronic cigarettes for smoking cessation. *Cochrane Database of Systematic Reviews*. Issue 10, Art. No.: CD004346. https://doi.org/10.1002/14651858.CD010216.pub4

Included 50 completed studies, representing 12,430 participants, of which 26 are randomized controlled trials (RCTs). Thirtyfive of the 50 included studies were new to this review update. There was moderatecertainty evidence that e-cigarettes (with nicotine) increase quit rates compared to e-cigarettes without nicotine and compared to NRTs. Evidence comparing e-cigarettes (with nicotine) with usual care/no treatment also suggests a benefit, but it was less certain.

2. Grabovac, I., Oberndorfer, M., Fischer, J., Wiesinger, W., Haider, S., & Dorner, T. E. (2021). Effectiveness of electronic cigarettes in smoking cessation: A systematic review and meta-analysis. *Nicotine & Tobacco Research*, *23*(4), 625–634. https://doi.org/org/10.1093/ntr/ntaa181

The search yielded 13,950 publications with 12 studies being identified as eligible for systematic review (N = 8,362) and 9 for random-effects meta-analyses (range: 30 to 6,006 participants). The results suggest that e-cigarettes (with nicotine) may be more effective in smoking cessation when compared to placebo electronic cigarettes or NRT. When compared to counseling alone, e-cigarettes (with nicotine) are more effective short term, but its effectiveness appears to diminish with later follow-ups.

Level of Evidence: Level I: systematic review

Recommendations: There is moderate-certain evidence that e-cigarettes (with nicotine) increase smoking cessation rates. Though there is some research to suggest that quit rates are short term, the combination of counseling and adjunct therapies might assist individuals long term. You include these findings in your presentation to the community along with additional information on counseling services as well as adjunct nicotine therapies to help reach smoking cessation.

All health care providers should recommend that a carbon monoxide (CO) detector be installed to alert family members to toxic levels of the gas. Gas or oil companies and the local health authority can help identify and remove sources of contamination. Many states and communities now require installation of CO detectors in residences. (See Box 28-1, page 841, for additional tips for preventing poisoning.)

Nursing Advocacy in Action

PATIENT SCENARIO

Ms. Jackson was admitted to the labor and delivery unit in active labor. She is in prison for killing her husband and is accompanied to the hospital by two armed guards. She is in shackles in the labor room “to prevent her escape.” When you begin your shift, you find a woman in hysterics who has been in labor for 12 hours because of the position of the baby. You want to get her shackles off to try to make her more comfortable, but the guards aren’t willing to help. They explain that it is policy to keep them on for felons like Ms. Jackson. You are horrified.

IMPLICATIONS FOR NURSING ADVOCACY

How will you respond if you are Ms. Jackson’s nurse? Talk with your classmates and experienced nurses about the questions that follow:

- If you elect to advocate for Ms. Jackson and other women like her, what practical steps can you take to reflect your moral agency and work to develop policies and procedures that meet the requirements of law enforcement, but allow for compassionate, person-centered nursing care?
- What is reasonable to expect of a student nurse, a graduate nurse, and an experienced nurse in this situation?
- What advocacy skills are needed to effectively respond to this challenge?

Most exposures to toxic fumes occur in the home. Poisoning may result from improper mixing of household substances, prolonged use of strong cleaning products, or malfunctioning household appliances (gas, oil, and kerosene heaters) that can release CO. CO is a poisonous gas that is also colorless, odorless, and tasteless, which makes it especially dangerous. Exposure can result in mild symptoms or progress to a life-threatening problem or long-term effects. CO toxicity can cause severe organ damage in a very short period of time. More than 150 people in the United States die each year from (non–fire-related) accidental CO poisoning (U.S. Consumer Product Safety Commission, n.d.).

Nurses need to review existing fire prevention strategies and escape plans in their home safety assessment. Ensuring homes have a working, high-quality smoke alarm that is tested regularly is the highest priority. Box 28-1 (on page 841) lists important fire safety issues as well as other safety issues that should be addressed when assessing for risk factors in the home. Fire, injury from fire, and fire-related deaths increased by 2% from 2008 to 2017 but are still less than a third the rate in the late 1970s. Based on data collected by the U.S. Fire Administration (2019), residential fires (29%) are second in prevalence only to outdoor fires (43%). It is important to note that 78% of all fire deaths occur in the home (U.S. Fire Administration). Cooking is the leading cause of residential building fires (52%). Heating caused 9% of residential fires. Residential fires that result in fatalities are most often related to careless actions (17%), followed by causes under investigation (14%), intentional actions (13%), and smoking (12%; U.S. Fire Administration). Most fatal home fires occur while people are sleeping, and most people who die in house fires die of smoke inhalation rather than burns. The widespread availability and use of home smoke alarms is considered the primary reason for the significant decline in fire-related injury and death. Low-cost smoke alarm options increase home-prevention accessibility for all people, including those for whom cost is a consideration. Work is being done to fine-tune smoke detectors to minimize nuisance alarms that sound with the detection of any smoke aerosol particles, even those created by routine cooking. This is important because these nuisance alarms result in people disconnecting the wires or removing the batteries from their smoke alarm, thereby rendering it useless (Warmack et al., 2015).

Accidents in the home frequently result from careless use of equipment or from malfunctioning or poorly maintained equipment. Many injuries and deaths from electric shock can be prevented. Overloaded electrical circuits, faulty appliances, frayed wires, careless use of electrical equipment, and handling of electrical devices and cords with wet hands or while wearing wet shoes can result in injury or death. (See Box 28-1, page 841, for specific guidelines to prevent electrical injury.)

Functional Ability

Mobility

Any limitation in mobility is potentially unsafe. An older adult with an unsteady gait is more prone to falling. Furthermore, if the patient is in an unfamiliar setting, such as a health care facility, the problem may be aggravated. Someone with paralysis or a spinal cord injury may require assistance with even simple movements. Supportive devices —such as canes, walkers, and wheelchairs—may facilitate movement, but they require careful patient instruction and preparation for safe use. Recent surgery or a prolonged illness can temporarily affect a patient's mobility and necessitate special precautions to prevent falls or injuries. Nurses must assess a patient's risk for injury with a view toward maintaining independence and fostering self-esteem while providing a safe and predictable environment.

Think back to **Bessie Washington**, the 77-year-old woman who experienced a stroke, lives alone in a small apartment, and requires a walker to ambulate. To ensure that the patient remains safe, the nurse needs to assess the patient's home environment closely for hazards. This is especially important for Bessie based on her statement that she almost fell recently.

Sensory Perception

Alterations in sensory perception can have a devastating effect on safety. Any impairment in sight, hearing, smell, taste, or touch can reduce a person's sensitivity to the environment. Vision changes may cause a person to stumble, lose their balance, and fall. In 2014, a CDC analysis determined that the state-specific annual prevalence of falls among older adults (age >65 years) with severe vision impairment ranged from 30.8% to 59.1%. Prevalence of falls in older adults without severe vision impairment ranged from 20.4% to 32.4% (Crews et al., 2016). Declines in visual acuity, contrast sensitivity, depth perception, visual field, and visual motion perception related to the illusion of self-motion, postural

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

control, and balance control all contribute to the risk of injury related to visual changes (Saftari & Kwon, 2018). A patient with a hearing deficit may not be able to hear safety alarms, automobile horns, or sirens and may not hear health care instructions. A patient with a reduced ability to distinguish odors may fail to detect leaking gas or smoke. A patient with a loss of taste may have unsafe eating habits or may eat tainted food. A patient whose tactile sense is impaired may not perceive temperature extremes that are a threat to safety.

Ability to Communicate

The ability to communicate is basic to many safety practices. The nurse must assess any factor that influences the patient's ability to receive and send messages. Fatigue, stress, medication, aphasia, and language barriers are examples of factors that can affect personal communication and prevent the patient from accurately perceiving events. For example, a medication side effect of drowsiness may interfere with a health teaching session between the nurse and the patient taking this medication. A valid assessment by the nurse not only identifies the patient's level of understanding, but also facilitates a positive communication experience.

Knowledge

An awareness of safety and security precautions is crucial for promoting and maintaining wellness throughout the lifespan. For example, patients need instructions to adhere to a medical regimen or to follow safety precautions when oxygen is in use. They require a certain amount of knowledge to manage new equipment and unfamiliar procedures. Nursing assessment includes identifying and recognizing potentially threatening circumstances caused by a lack of knowledge regarding safety and security precautions. Patient teaching about safety is crucial and must be individualized, take into account health literacy, and be leveled appropriately for patients and families.

Recall **Juanita Flores**, the young mother of the 1-year-old who fell from a cot. The nurse's knowledge of potential threats to safety for infants, in conjunction with providing anticipatory guidance to the mother about safety issues for infants, would be essential to prevent future potential injury.

Health

Physical Health State

When a person is chronically ill or in a weakened state, the focus of health care includes preventing accidents as well as promoting wellness and restoring the person to a healthy state. For example, the nurse caring for a patient who is recovering from a stroke (cerebral vascular accident) identifies the patient's neuromuscular impairment, pays particular attention to health teaching concerning the person's ability to maintain a sense of balance, and carefully assists the patient with ambulation to prevent falls. Many patients who fall have a primary or secondary diagnosis of cardiovascular disease. Prevention of complications and return to the optimal level of functioning require attention to safety and become primary concerns in a rehabilitation program. The nurse strives to maximize the patient's potential by considering safety factors in all phases of the illness and recovery experience.

Examples of Actual or Potential Health Problems and Needs

SAFETY AND SECURITY

Actual or Potential Health Problems and Needs	Possible Etiologic Factors	Potential Signs and Symptoms
Risk for Fall	• Absence of stairway gate or window guard (children) • Difficulty with gait • Inadequate supervision • Insufficient knowledge of modifiable factors	—

	• Unsafe home environment	
Risk for Poisoning	• Access to dangerous product • Access to pharmaceutical agent • Insufficient knowledge of pharmacologic agents • Occupational setting without adequate safeguards • Insufficient vision	—

Source: International Council of Nurses (ICN). (2019). *Nursing diagnosis and outcome statements*. https://www.icn.ch/sites/default/files/inline-files/ICNP2019-DC.pdf

Consider **Bessie Washington**, the woman who is now at home after having a stroke. The nurse would incorporate knowledge of safety factors along with knowledge of Bessie's mobility limitations to develop a plan of care that maximizes her potential while maintaining her safety.

Psychosocial Health State

Stressful situations tend to narrow a person's attention span and make the person more prone to accidents. Stress may occur over a long period, but the effects tend to be more devastating in the person's later years, when there is typically less adaptive and coping capacity. Depression may result in confusion and disorientation, accompanied by reduced awareness or concern about environmental hazards. Social isolation or lack of social contact may lead to a reduced level of concentration, errors in judgment, and a diminished awareness of external stimuli.

Nursing Process

An assessment of the patient may lead to the identification of one or more diagnoses or patient problem related to actual or potential safety issues. Following the formulation of the diagnoses or patient problems, the nurse communicates findings to other nursing and health care professionals through the use of the written and spoken word. The written diagnosis or patient problem becomes a permanent part of the patient's health record. Examples of health problems and needs with related etiology and signs and symptoms can be found in the box titled Examples of Actual or Potential Health Problems and Needs: Safety and Security.

Many accidental injuries and deaths are preventable. Consider the various factors and the environment that affect the patient's safety, and formulate expected outcomes uniquely suited to each situation and circumstance. Nursing interventions focus on meeting these safety needs. Some expected outcomes for patients that promote safety and prevent injury are as follows.

The patient will:

- Identify unsafe situations in their environment
- Identify potential hazards in their environment
- Demonstrate safety measures to prevent falls and other accidents
- Establish safety priorities with family members or significant others
- Demonstrate familiarity with their environment
- Identify resources for safety information

Nursing interventions are designed for each developmental level as well as for specific hazards in the environment. Adults who are developmentally disabled or who are experiencing dementia or delirium may require the same safety measures typically considered for children. Injury control includes preventing injuries, providing acute care for injured patients, and rehabilitation services. The emphasis needs to be on injury prevention, which promotes the reduction of injuries through eliminating risky events, measuring the consequences of these events, and reducing the severity of injuries. Skill 28-1 on pages 871–872 demonstrates the proper method for performing a situational assessment. Interventions that include modification of the environment and education for at-risk people have proven effective.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Teaching is an important intervention for accident prevention and health promotion. Many teaching opportunities concerning safety measures arise while the nurse performs regular patient care, and many resources are available to supplement health teaching (Fig. 28-2). Also, remember that nurses who role model good health behaviors are more effective teachers. Careful assessment, diagnosis, and planning prepare nurses to use these opportunities wisely. Assessment data and statistical information often provide helpful information for health care personnel who are developing a safety program for patients at risk. Safety education classes, in addition to situational health teaching, can be worthwhile for hospitalized patients and their family members. Studies have demonstrated that early assessment of vulnerable patients and preventive education programs can decrease the incidence of falls and promote safety.

FIGURE 28-2. The nurse's responsibilities in home safety are primarily that of education and counseling, including providing information about home safety devices and sources for additional information. (*Source:* C. Courtesy of K. Bartlett.)

Evaluation is the final step of the nursing process. Nurses must evaluate the effectiveness of their interventions to promote environmental safety, prevent injury, and promote emergency preparedness. If the expected patient outcomes have been met and evaluative criteria have been satisfied, the patient should be able to accomplish the following:

- Correctly identify real and potential unsafe environmental situations
- Implement safety measures in the environment
- Use available resources to obtain safety information
- Incorporate accident prevention practices into activities of daily living
- Remain free of injury

ASPECTS OF SAFETY AND SECURITY

All four spheres of practice-prevention and promotion of health and well-being, chronic disease care, regenerative (critical and trauma) care, and hospice and palliative care (American Association of Colleges of Nursing, 2021)-involve interactions with patients, families, and communities where safety and security must be considered. Health care encompasses interactions that occur in primary, secondary, and tertiary settings. This section will highlight these points of contact and specifically consider the acute care (hospital) setting as an exemplar.

Patient Safety

Admission to a heath care facility requires intentional consideration of person-centered risks and injury prevention strategies. The initial assessment performed by the nurse upon admission to a health care facility summarizes all of this information (refer to Nursing History in Chapter 15).

Recall **Bessie Washington**, the older adult woman described at the beginning of the chapter. Based on the assessment of the patient, the nurse would identify Bessie's risk for falls as high. It would be crucial to incorporate this information into her plan of care to ensure her safety.

Orienting the Person to Surroundings

A person who is familiar with one's surroundings is less likely to experience an accidental injury. As part of the hospital admission routine, orient the patient to the safety features and equipment in the room. An explanation and demonstration of the adjustable bed and side rails, call system, telephone, television, and bathroom help the patient adjust to the new environment. The patient identification bracelet and a discussion of facility routine further ensure safety and assist the patient to adapt to the unfamiliar setting. Disruption in routine, unfamiliar surroundings, competing priorities, and the physiologic and psychological effects of illness contribute to the stress experienced by all patients. Use this orientation as an opportunity to demonstrate the importance of orienting an older adult to new surroundings when the older adult moves in with a family member or moves to a new residential community.

Technology Alert

As part of the admission process, many electronic health records (EHRs) have embedded one or more questions regarding safety: *Do you feel safe in your home? Do you feel safe in your relationships? Do you feel like you may be in danger in your home?* The challenge for providers is to attribute meaning and context for these questions, and to ask them at an appropriate time (Hunt et al. 2017).

Preventing Falls in the Health Care Facility

Health care facilities have fall prevention programs that are enacted for the duration of the patient's stay and are designed to facilitate discussion regarding safety at home and in the community. National initiatives encourage health care providers to ask these three questions at every encounter with older adults:

. Have you fallen in the past year?
. Do you feel unsteady when standing or walking?
. Do you worry about falling?

Figure 28-1 (on page 850) depicts the CDC's STEADI decision-making algorithm for determining and addressing fall risk. Nurses are responsible for identifying patients who are at high risk for falls, documenting pertinent assessments on the chart, and planning appropriate interventions to ensure their safety. A nurse whose behavior is reasonable, prudent, and similar to the behavior that would be expected of another nurse in similar circumstances is unlikely to be found liable if a patient falls, even if the fall results in an injury.

Concept Mastery Alert

Of the many ways to avoid falls in the acute care setting, the best outcome for a patient at risk for falling is that the patient will not experience a fall and remains free of injury.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

The Joint Commission requires that hospitals implement fall prevention assessments and programs; they also require reporting, with a root cause analysis, of falls deemed a **sentinel event**, which is an unexpected occurrence involving death or serious physical or psychological injury, or the risk of death or injury (The Joint Commission, 2022c); see "Sentinel Events" on page 164 in Chapter 7, Legal Dimensions of Nursing Practice. The Centers for Medicare and Medicaid Services (CMS) has identified falls as a *never event* (medical error that should never occur) and includes falls and trauma on its list of Hospital Acquired Conditions (HAC) for which reimbursement will be limited, specifically for falls that result in fractures, dislocations, and/or intracranial injuries (U.S. Department of Health and Human Services, Agency for Healthcare Research and Quality, 2019b). Safety measures recommended to reduce the number of falls in acute and extended-care facilities are given in Box 28-5.

Box 28-5 Nursing Interventions to Prevent Falls in a Health Care Facility

- Complete a risk assessment.
- Indicate risk for falling on patient's door and chart.
- Keep bed in low position.
- Keep wheels on bed and wheelchair locked.
- Leave call bell within patient's reach.
- Instruct patient regarding use of call bell.
- Answer call bells promptly.
- Leave a night light on.
- Eliminate all physical hazards in the room (clutter, wet areas on the floor).
- Provide nonskid footwear.
- Leave water, tissues, bedpan/urinal within patient's reach.
- Move bedside commode out of sight to discourage attempts at independent transfer (as appropriate).
- Document and report any changes in patient's cognitive status to the health care team at the change of shift.
- Use alternative strategies when necessary instead of restraints.
- As a last resort, use the least restrictive restraint according to facility policy.
- If restraint is applied, assess patient at the required intervals.

A simple evaluation tool can help identify hospitalized patients at risk for falling. According to accreditation standards, the Hendrich II Fall Risk Model™ , which can be administered quickly, evaluates eight independent risk factors. This tool also includes the Get Up and Go Test that measures a person's ability to rise from a seated position. Performance on each physiologic factor merits a specific score and identifies those most at risk for falls. The Morse Fall Scale is another tool frequently used. Institutions can use the score on the Morse Fall Scale, derived from the answers to six questions, to identify patients at risk for falls. View the Hendrich II Fall Risk Model™ and the Morse Fall Scale in Student Resources online for this text.

In response to The Joint Commission's mandate that accredited health care organizations must reduce the risk of harm to patients resulting from falls, hospitals have implemented effective programs to safeguard their patients from falls. Examples of these improvement strategies include:

- *Preventing Falls Targeted Solutions Tool (TST)*: An online application from The Joint Commission for Transforming Healthcare (2022) that provides a systematic approach to reduce the rate of falls.
- *Falls Toolkit*: A comprehensive toolkit that contains elements such as a falls notebook (with instructions, policies, and training materials), post-fall huddle guides, hospital/staff/community assessment tools, podcasts, website links, and other tools (U.S. Department of Veterans Affairs, 2019).
- *Falls Prevention Training Program:* A program highlighting the importance of staff orientation and periodic, ongoing training; includes education for staff on the intrinsic and extrinsic risks of falling, environmental assessments, and falls prevention strategies (ECRI, 2018).
- *Root Cause Analysis (RCA):* A tool used to study health care–related (actual) *adverse events* and *close calls*. The RCA process is designed to find out what happened, why it happened, and how to prevent it from happening again. The RCA process supports the development of a culture of safety at an institution (United States Department of Veteran Affairs, 2018).

Polypharmacy has long been listed as a risk factor for falls—the changes in medication regimen while hospitalized further compound this issue. Research indicates that adverse effects related to the specific medication categories of antiepileptics and benzodiazepines are more predictive of falling. Some common safety devices used in health care facilities are shown in Figure 28-3.

FIGURE 28-3. Some of the safety devices used in health care facilities and in the home to prevent falls. **A.** Side rails on bed raised at the patient's request; the patient must be able to raise and lower the side rail without help. **B.** Locking devices on wheeled equipment. **C.** Nonskid slippers. (*Source:* Used with permission from Shutterstock. *Photos by B. Proud)*.

FIGURE 28-4. Restraints used for adults and children. The purpose of restraints is to help prevent the patient from being harmed. Restraints should not interfere with physiologic functioning by impairing circulation, limiting muscular activity to the point of immobilization, or interfering with respiration. Restraints that can be adjusted to the desired activity limitation are most likely to be accepted by the patient and family.

Unfolding Patient Stories: Josephine Morrow • Part 2

Recall from Chapter 24, **Josephine Morrow**, an 80-year-old with a venous stasis ulcer on her lower extremity who recently moved to a skilled nursing home. She has an unsteady gait and forgets to call for assistance when getting out of bed. How can the nurse promote patient safety and prevent falls? Why would the nurse refrain from using restraints for Josephine?

Care for Josephine and other patients in a realistic virtual environment: *vSim for Nursing* (thepoint.lww.com/vSimFunds). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

Using Restraints in Health Care Facilities

Restraints are physical devices or chemical means used to limit a patient's freedom and movement that cannot be easily removed (or eliminated) by the patient. Side rails, geriatric chairs with attached trays, and appliances tied at the wrist, ankle, or waist are types of physical restraints. Figure 28-4 shows examples of physical restraints that can be used for adults and children. Drugs that are used to control behavior and are not included in the person's normal medical regimen can be considered chemical restraints.

In the past, it was considered acceptable bedside care to restrain patients to protect them from harm, but the use of restraints for this purpose is potentially dangerous. Physical restraints can increase the possibility of serious injury due to a fall—they do not prevent falls. Negative outcomes of restraint use include skin breakdown and contractures, incontinence, depression, delirium, anxiety, aspiration and respiratory difficulties, and even death. Older adults with dementia are most at risk of being restrained, in general; in the ICU setting, younger adults are restrained at approximately the same rate as older adults. The use of restraints is declining as health care providers become more educated about the risks associated with their use.

Since 1987, the federal government and accrediting agencies have worked to reduce or eliminate the use of restraints. Initial guidelines formulated by the Health Care Financing Administration as part of the 1987 Omnibus Budget Reconciliation Act encouraged the limited use of restraints in long-term settings. The current standard for long-term care facilities is to provide safe care without the use of physical or chemical restraints. Federal and state mandates, as well as The Joint Commission, recommend that acute care facilities use restraints only as a last resort.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Federal guidelines reinforce that in all settings, the primary responsibility is to protect and promote patient's rights, and that restraints may only be used to protect the patient, staff, or others. They must be discontinued at the earliest possible time. Any health care facility that accepts Medicare and Medicaid reimbursement must abide by the federal guidelines for the use of restraints. In addition to labeling preventing falls and fall-related injuries a sentinel event (Sentinel Event Alert #55), The Joint Commission (2022c) identified preventing restraint death as a sentinel event (Sentinel Event Alert #8). These events signal the need for an immediate investigation and response. The American Nurses Association (2012) approved a revised position statement defining the nurse's role in reducing restraint use in health care. Their recommendations are included in Box 28-6 on page 860.

USING SIDE RAILS AS A RESTRAINT

In the past, side rails were used to provide support and aid equilibrium, but it is now recognized that they can pose serious risks for a confused or agitated patient. A 1995 FDA Safety Alert informed health care facilities of the hazards associated with side rail use. A person of small stature has a greater risk for entrapment or injury. Death from asphyxiation has occurred when patients have become wedged between the mattress and the bed frame or side rail. Although patient entrapment is uncommon, it can be fatal. Most of the victims of side rail fatalities are frail, of advanced age, or confused, and many exhibit uncontrolled body movement. Most incidents of entrapment occur in a long-term care setting.

A side rail is not considered a restraint if the patient requests that it be raised to aid in getting in or out of bed. Some patients may request that side rails be used at night while they sleep so that they feel more secure (see Fig. 28-3A on page 858). Patients requesting side rails must be able to raise and lower the side rails themselves. Side rails that are raised with the *intent* to prevent the patient from voluntarily attempting or actually getting out of bed, would be considered a restraint; if the *intent* of raising the side rails is to prevent a patient from inadvertently falling out of bed, or if the patient lacks the physical ability to even attempt to get out of bed, side rails would not be considered a restraint (The Joint Commission, 2021). If a family member requests the use of side rails for a patient, it is the nurse's responsibility to review benefits and risks associated with their use and periodically evaluate the reason for their use. Side rails are not routinely recommended for all situations. It is the responsibility of health care facilities to evaluate existing bed systems for entrapment risks and investigate corrective actions that may be necessary to provide a safe environment for patients.

Box 28-6 **American Nurses Association (ANA) Board of Directors Position Statement: Reduction of Patient Restraint and Seclusion in Health Care Settings**

Recommendations: To ensure safe, quality care for all patients in the least restrictive environment, ANA supports nursing efforts to:

1. Educate nurses, nursing students, assistive personnel, other members of the interdisciplinary team, and family caregivers on the appropriate use of restraint and seclusion, and on the alternatives to these restrictive interventions;
2. Ensure sufficient nursing staff to monitor and individualize care with the goal of only using restraint when no other viable option is available;
3. Ensure policies and environment support services are in place to provide feasible alternatives to physical and chemical restraints;
4. Move progressively toward a restraint-free environment while providing a therapeutic sanctuary for all;
5. Enforce documentation requirements and education about what should be documented;
6. Explore the ethical implications of restraining patients with nursing students and discuss the need for institutional policy that clarifies when, where, and how patients are to be restrained and monitored while restrained;
7. Be aware of all implications of allowing the application of restraints in health care settings. The nurse administrator should make consultation available to nurses, including ethical consultation about decisions to restrain; and
8. Develop clear policies based on accepted national standards to guide decision making regarding restraints.

Source: American Nurses Association. (2012, March 12). *Reduction of patient restraint and seclusion in health care settings*. https://www.nursingworld.org/~4af287/globalassets/docs/ana/ethics/ps_reduction-of-patient-restraint-and-seclusion-in-health-care-settings.pdf

Box 28-7 **Choosing Alternatives to Restraints**

- Determine whether a behavior pattern exists.
- Assess for pain and treat appropriately.
- Rule out causes for agitation. Assess respiratory status, vital signs, blood glucose level, fluid and electrolyte issues, and medications. Use standardized screening tools to evaluate change in function.
- Involve the family and other people important to the individual in the patient's care.
- Ask family members or significant other to stay with the patient.
- Reduce stimulation, noise, and light.
- Distract and redirect, using a calming voice.
- Use simple, clear explanations and directions.
- Check environment for hazards.
- Use night light.
- Identify door of room (e.g., use of balloon, sign, patient's picture, ribbon).
- Use an electronic alarm system on a temporary basis (e.g., bed or position-sensitive alarms) to warn of unassisted activity.
- Allow restless patient to walk after ensuring that environment is safe.
- Use a large plant or piece of furniture as a barrier to limit wandering from designated area.
- Use low-height beds.
- Place floor mats on each side of the bed.
- Ensure the use of glasses and hearing aids, if necessary.
- Use pillows wedged against the side of the chair to keep patient positioned safely.
- Use full-length body pillows, a swimming pool noodle, or a rolled blanket to indicate the edge of the bed.
- Assist with toileting at frequent intervals.
- Arrange for a bedside commode.
- Make the environment as homelike as possible; provide familiar objects.
- Provide a warm beverage.
- Provide comfortable rocking chairs.
- Use therapeutic touch.
- Play music or video selections of the patient's choice.
- Offer diversional activities, such as games and books.
- Encourage daily exercise/provide exercise and activities or relaxation techniques.
- Consider relocation of the patient to a room closer to the nursing station.
- Conceal tubing necessary for care. Anchor tubing securely. Conceal tubing with gauze wrap; unwrap regularly to assess site for complications.
- Investigate possibility of discontinuing bothersome treatment devices (e.g., intravenous line, catheter, feeding tube).

USING ALTERNATIVES TO RESTRAINTS

Careful nursing assessment is the key to identifying appropriate alternatives to restraint use and finding an individualized solution (Box 28-7). Nursing interventions may be used to reduce confusion or agitation and provide a safe environment. Using a restraint on an older adult who tends to wander is unjustified because a variety of alternative options can be used to keep such patients safe. Figure 28-5 shows an example of a position-sensitive electronic device that is an alternative to using restraints. A variety of electronic alarms and monitors are available for chairs, beds, and doors.

FIGURE 28-5. Ambularm device. (*Source:* Reprinted with permission of AlertCare, Inc.)

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

USING RESTRAINTS AS A LAST RESORT

Despite all efforts, restraints may be the only solution in some situations. The least restrictive restraint should be the first option. Restraints must never be applied for the convenience of the staff. The patient's family must be consulted and involved in the plan of care before applying restraints in a long-term care setting. They must be informed of the facility's policy regarding applying and removing restraints and may be asked to sign a release form to protect the facility from liability. Facility policy, The Joint Commission, and state and federal guidelines require an order from a provider permitted to provide specific oversight of restraints, such as a physician or other licensed practitioner (U.S. Department of Health and Human Services, Centers for Medicare and Medicaid Services, 2019). The order should include the type of restraint, justification for the restraint, and criteria for removal. The order must never be written for PRN (as needed) use.

In an emergency, the physical restraint can be applied if an established protocol is followed, but an order from a provider must be obtained immediately or within a few minutes according to Joint Commission Standards. The order must state the intended duration of use. The patient must be monitored and assessed at least every hour or according to facility policy. An inpatient psychiatric patient in restraints requires continual observation, including specific assessments every 15 minutes. Initial documentation must reflect the date and time the restraint is applied, the type of restraint, alternatives that were attempted (including their results), and notification of the patient's family and health care provider. Ongoing documentation includes the frequency of assessment and release intervals, assessment findings, and other nursing interventions such as toileting. Constant reevaluation of the need for the restraint is vital. Chapter 7 discusses the legal issues involved when restraints are used. Student nurses, from their earliest clinical experiences, need help to identify and assess the cause of a patient's behavior and not just the behavior itself. Careful patient assessment is needed to develop creative alternative strategies. Skill 28-2 on pages 873–876 demonstrates the proper method for applying restraints should they be necessary.

Concept Mastery Alert

Restraints may be applied, per protocol, without a provider's order only if the situation is an emergency and the threat to safety is imminent. However, restraints should only be used as a last resort and an order must be obtained immediately afterward.

Facility Safety

In addition to individual patient safety, the safety of the facility itself and its employees must also be intentionally considered—establishing a safe and secure environment promotes the delivery of safe, quality care. Laws or regulations, such as those imposed by Occupational Safety and Health Administration (U.S. Department of Labor, OSHA, 2016), help promote modification of at-risk behavior of health care workers. Initiatives that consider smooth transitions of care (see Chapter 12, Interprofessional Collaborative Practice and Care Coordination Across Settings) promote safety as patients navigate the complex health care system. An agency's policies and procedures foster the development and maintenance of a safe, predictable work environment, and provide recourse for employees should actions potentially or actually affect the safety of patients, health care workers, or the communities they serve.

Fire Safety

Fire prevention and emergency response programs in health care facilities are sometimes viewed by staff as time-consuming or unnecessary exercises, but nurses must be prepared at all times to protect patients from injury. Hospitals are required by law to establish safety boards and to inspect the facility regularly for possible hazards. Equipment must be checked periodically, and escape routes must be kept open. Nurses, as part of their daily care procedures, must be aware of their facility's policies, review equipment and its proper functioning, and assess when and how often drills are performed.

Careless smoking, faulty electrical equipment, and combustion of anesthetic agents are the most common causes of hospital fires. Orientations in health care facilities emphasize fire prevention information and the facility's smoking policy. Nurses are responsible for patients' safety and need to be familiar with the facility's fire safety plan, exits, the location and operation of fire extinguishers, and any special instructions for reporting a fire.

Most hospital procedures emphasize the following priorities and recommend that staff members remember the acronym RACE as a guide:

- **R**escue anyone in immediate danger
- **A**ctivate the fire code system and notify the appropriate person
- **C**onfine the fire by closing doors and windows
- **E**vacuate patients and other people to a safe area

ABC (universal, dry chemical) fire extinguishers are the most common extinguishers used in health care facilities. In the home setting, cigarettes, grease, and electrical problems are most often responsible for fires. Educating parents about home fire safety includes having a plan of action similar to that used in health care settings. (See Box 28-1, on page 841, for priorities and practical suggestions for fire and burn safety.)

Alarm Management

The hospital is a very noisy place, but that is sometimes necessary. Overhead announcements that are fairly universal cue health care staff to a variety of events such as a medical emergency (Code Blue), child abduction (Code Pink), a bomb threat (Code Black), or even hazardous spill (Code Orange; The Joint Commission, n.d.). There are also almost ubiquitous alarms from any variety of monitoring systems throughout the hospital. Staff conversations and medical device alarms contribute to the cacophony of sounds that can be disconcerting to patients, at the very least, and perhaps even detrimental to their health and healing. Safety initiatives have focused on improving the hospital soundscape by training staff in noise reduction, enforcing noise reduction programs (such as the quiet time instituted on some units to allow for an afternoon respite for patients), rethinking and reworking alarms and considering their necessity in the clinical setting to decrease desensitization and alarm fatigue of staff, and researching the effects of noise on patient and staff (Oleksy & Schlesinger, 2019).

Preventing Equipment-Related Accidents

With the marked increase in the use of highly sophisticated electronic equipment in health care settings, all members of the health care team must learn to use the equipment properly and recognize signs of malfunctioning equipment. Suction devices with inadequate vacuum, and rate regulators or infusion pumps that deliver erratic amounts of solution, have resulted in equipment-related accidents. Failure to use protective belts or side rails on stretchers and to lock wheelchair wheels can result in patient injury.

Electrical equipment can present a safety hazard to both the patient and health care practitioner when safety measures are ignored. Most electrical equipment used in hospitals is equipped with three-prong plugs. The third prong, when inserted into a properly wired wall outlet, provides a ground for the piece of equipment. A ground is a connection from an electricity source to the earth through which electric current leakage can be harmlessly conducted. Box 28-8 lists guidelines to help reduce the number of equipment-related accidents. Hospitals and long-term care facilities are required by federal law and U.S. Food and Drug Administration (FDA, 2019) regulations to report to the FDA and the manufacturer of a device any suspected deaths or serious injuries related to use of the device.

Box 28-8 Decreasing Equipment-Related Accidents

- Use equipment only for the use for which it was intended.
- Do not operate equipment with which you are unfamiliar.
- Handle equipment with care to prevent damaging it.
- Use three-prong electric plugs whenever possible.
- Do not twist or bend electric cords. The wires inside the cord may break.
- Be alert to signs that indicate equipment is faulty such as breaks in electric cords, sparks, smoke, electric shocks, loose or missing parts, and unusual noises or odors. Report signs of trouble immediately.
- Make certain that electric cords are not in a position to be trapped as beds are raised or lowered. This can strip insulation covering the electric wires.
- Be alert for wet surfaces on areas where electric cords or connections are present.
- Make certain when charging defibrillator batteries that charging indicator light is on.
- Implement a process for reporting and addressing problems with equipment.

Preventing Procedure-Related Accidents

The nurse must always be cautious and alert to prevent procedure-related accidents. Errors are possible when administering medications or intravenous solutions, transferring a patient, changing a dressing, or applying external heat to a patient's extremity. Therefore, nurses must follow correct procedures when administering care. Safeguards to prevent errors include making sure that the patient is identified correctly (Fig. 28-6), calling a time-out in the operating suite, and following protocols and policies designed to protect patients.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 28-6. An essential nursing responsibility is checking the patient's identification bracelet before any procedure. Here, the nurse checks the patient's identification before administering medications.

In an effort to promote a culture of safety, The Joint Commission (2022b) publishes an annual list of National Patient Safety Goals. These are established based on sentinel events that have been reported and include the corrective actions recommended as a response to these sentinel events. Some goals are ongoing while others may get removed from the annual list once hospitals have incorporated the recommended practices to meet a particular safety goal into their standards of operation. The goals and related requirements are specific to each accreditation program (e.g., ambulatory care, assisted living, long-term care). Accreditation by The Joint Commission requires that a health care organization provide evidence that these goals have been addressed and requirements have been met. Effective alternatives may be acceptable, depending on the services provided by the particular health care organization. National Patient Safety Goals are available on The Joint Commission website at http://www.jointcommission.org/standards_information/npsgs.aspx (see Additional Resources).

Filing a Safety Event Report

An accident or incident that compromises safety in a health care facility requires the completion of a **safety event report**.

Recall **Juanita Flores**, the young mother whose child fell off the cot. As a result of the fall, a safety event report was completed.

This is a confidential document, formerly referred to as an incident report, which objectively describes the circumstances of the accident or incident. The report also details the patient's response and the examination and treatment of the patient after the incident. The nurse completes the event report immediately after the incident and is responsible for recording the circumstances and the effect on the patient in the medical record. The safety event report is not a part of the medical record and should not be mentioned in the documentation. Because laws vary by state, nurses must know their own state law regarding safety event reports. All safety event reports are reviewed carefully to detect any potentially threatening situation or pattern. These reports are discussed in more detail in Chapter 7. When an incident results in a patient injury, the nurse has a responsibility to speak openly and honestly with the patient and family.

POPULATION-BASED ASPECTS OF SAFETY AND SECURITY

Ideally, the nurse, the patient, and the family should work together to eliminate or reduce accident risks in the home and health care setting. Engagement with partners in the community, provides nurses the opportunity to impact change at the local, state, national, and global levels. Nationally, community-based nurses and emergency nurses are establishing partnerships and venturing into the community to offer injury prevention activities to children and families. A good

resource for nurses is the CDC's WISQARS (Web-based Injury Statistics Query and Reporting System) available at http://www.cdc.gov/injury/wisqars. This site is an interactive, online database that provides fatal and nonfatal injury, violent death, and cost of injury data from a variety of trusted sources. Population health is interprofessional in nature and involves engaging at the community level to connect practice to policy. These interprofessional partnerships include public health experts, educators, industry leaders, health care providers, and government representatives. Population health initiatives focus on collaborative efforts of systems, agencies, and organizations to work together on resource allocation and community-based initiatives designed to overcome barriers and improve the health outcomes for a population (CDC, 2019f).

Safety in Schools

A school nurse has many opportunities and a ready audience for health teaching about safety, including screening programs (e.g., vision and hearing), fire prevention sessions, drug and alcohol prevention programs, firearm safety, and classes on various accident prevention techniques. Managing minor accidents at school often provides an opportunity for additional preventive teaching. In this setting, the school nurse has the opportunity for formal or informal health teaching with children and parents/caregivers that should include parental encouragement to do the following:

- Monitor the child's use of the Internet
- Get involved in school activities and ask pertinent questions
- Volunteer for safety committees that include staff and parents
- Ensure that the school's emergency preparedness plan is current

For many children, school meal programs effectively reduce food insecurity, support healthy development, address obesity, and promote learning. Need-based programs are historically based on the individual applying for free or reduced-cost school meals, but there is a move toward entire schools participating in *community eligibility*, a program that allows schools to offer both breakfast and lunch to all students at no charge. Districts that participate in this collaborative effort recognize the academic, health, and administrative benefits; participation of eligible schools rose by 6.6% from 2018 to 2019 (FitzSimons et al., 2020). Formal programs like this have the added benefits of minimizing the stigma for children unable to pay for meals (even at reduced prices) and demonstrating a mechanism by which to provide food to children when school has scheduled or unexpected closures (Food Research & Action Center, 2020). The Healthy, Hunger-Free Kids Act of 2010 was signed into law in 2010, but rules set forth by the United States that went into effect for the 2020–2021 school year relaxed some of the nutrition standards (U.S. Department of Agriculture, Food and Nutrition Service, 2018; U.S. Department of Agriculture, Food and Nutrition Service, 2020). It is important for nurses to appreciate their role in supporting or advocating changes to governmental rules, acts, and laws that determine nutrition and access standards for school breakfasts and lunches.

Schools are charged with creating a safe and supportive learning environment for students. Check out SchoolSafety.gov for action plans and resources on school safety topics including bullying and cyberbullying, threat assessment and reporting, security personnel, physical security and mental health, emergency planning with training and drills, school climate, and recovery.

Environmental Pollutants

Although much has been done to identify and control environmental pollutants, many U.S. residents still remain at risk for exposure to potentially unhealthy substances in the environment. In addition, certain environmental areas, such as dense urban areas, have proven to be more hazardous. Air pollution, in addition to its evidence-based link to climate change, has been shown to also increase the prevalence and severity of respiratory diseases, cardiovascular events, nervous system dysfunction, and diseases of the skin (Manisalidis et al., 2020; Vilcassim et al., 2019).

Community Violence

Living in an area where crime is prevalent can pose a threat to physical security and emotional well-being. Violence, acts of aggression, and terrorism are components of 21st-century life. Security measures such as locks, security systems, and exterior lighting can promote safety.

Home Health Nursing

It is imperative that nurses are aware of risks or hazards in certain settings that have the potential to result in violence and cause personal injury. Nurses include patient safety when assessing the home environment and neighborhood, and they consider access to and resources in the patient's community to develop a person-centered home health care plan. Nurses also need to consider their own safety. For example, in high-crime areas, a personal security escort may be provided to ensure a safe nurse visit (Irani et al., 2020). The Occupational Safety and Health Administration (U.S. Department of Labor, OSHA, 2016) identifies possible safety controls for home settings and specifies the use of a cell phone with GPS tracking, identification of exit routes and areas for patient de-escalation, assessment of outdoor and indoor lighting, use of a lock for supplies and equipment, and use of a well-maintained vehicle. Regulations also describe the responsibility of the employer to draft and enforce workplace violence policies, track workers, employ a system for documenting violent behavior of patients and families, provide a means for employees to receive backup

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

assistance, and provide discretion to the employee to leave the situation if they feel threatened or unsafe (U.S. Department of Labor, OSHA, 2016). Use Promoting Health 28-1 as a tool for self-evaluation of safety behaviors in the community setting before using it with others.

Promoting Health 28-1

SAFETY IN THE COMMUNITY

Use the assessment checklist to determine how well you are meeting your needs for maintaining personal safety as you assist with health care delivery in the community.

Assessment Checklist

☐ almost always	☐ sometimes	☐ almost never	
☐	☐	☐	1. I wear a badge or clothing that identifies me as a health care worker.
☐	☐	☐	2. I dress in an unobtrusive, professional manner with minimal jewelry.
☐	☐	☐	3. I keep my car in good working order.
☐	☐	☐	4. I am aware of neighborhoods where personal safety and security may be a problem.
☐	☐	☐	5. I notify my patient of my planned visit and confirm directions to the home.
☐	☐	☐	6. I communicate with my agency regarding the timing and location of my home visits.
☐	☐	☐	7. I request pets be secured before my visit.
☐	☐	☐	8. I assess the environment, noting lighting and establishing an exit strategy.
☐	☐	☐	9. I ensure equipment, supplies, and personal items are secured and not visible in my vehicle.
☐	☐	☐	10. I enter patients' homes only when invited in by a responsible adult.

Firearm Injuries

Preventing injuries caused by firearms has become a major concern for health care professionals. Intentional injuries caused by firearms are a leading cause of mortality in children. Some people believe that keeping a gun in the home provides protection for family and property. However, when a gun is available, it is more likely that the owner or a family member, rather than an intruder, will suffer a fatal injury. If not stored properly, guns can be extremely dangerous. Young children are curious and like to explore their surroundings—most children who die of unintentional firearm injury are shot by a peer in the same age range. When children encounter a loaded gun, even if instructed not to touch the weapon, the outcome is often tragic (Fowler et al., 2017). Also, having a gun in the house increases the risk for domestic homicide threefold.

Recent multivictim/mass shootings, gang violence incidents, activities related to drug procurement, interpersonal disagreements, and activities associated with law enforcement are examples of potential risks for injuries and fatalities associated with firearms. An estimated 4% of children ages 0 to 17 years in the United States in 2014 were in a place where they could see or hear people being shot, bombs going off, or street riots (Fowler et al., 2017)—this number may have increased since the mass, global protests in 2020 in response to the death of George Floyd and the call for police reform. Gun ownership is a sensitive issue; therefore, nurses need to approach this topic in a nonjudgmental manner with the focus on injury prevention. Nurses function as prevention partners by educating the public on the epidemic of gun-related injuries and deaths and informing families about the risks of firearm injury while discussing appropriate safety measures (see Box 28-1 on page 841).

Nurses are in a unique position to raise awareness and to help reduce high-risk behavior that may lead to firearm injuries and deaths. In homes, schools, and other health care settings, nurses can provide information on how parents/caregivers can keep guns out of the hands of children. Parents/caregivers may be unaware of how common gunshot injuries are or the dangers that can occur when a gun is accessible to children and young adults. Healthy People 2020 identified objectives related to injury and violence prevention, several of which involve the use of firearms. This is important because it identifies violence as a public health issue that needs to be addressed at the community level (U.S. Department of Health and Human Services, Office of Disease Prevention and Health Promotion, 2020b).

Emergency Preparedness

Emergency preparedness has always been a concern for health care workers. Nurses, as members of emergency response teams, need to be aware of their role when an emergency or disaster occurs. Existing community resources are usually sufficient to respond to an emergency situation, such as a multiple vehicle collision, a fire in an apartment complex involving a significant number of burn injuries, an explosion, or plane crash. Since the September 11, 2001, terrorist attacks in New York, Washington, DC, and Pennsylvania, attention has been focused on national security and strategies for sustaining emergency preparedness levels. These events highlighted the need for communities to step up the level of their involvement in emergency preparedness for any disaster.

A **disaster** is broadly defined as a tragic event of great magnitude that requires the response of people outside the involved community. Disasters can be categorized as natural (e.g., massive flooding following a hurricane or an earthquake) or manmade (e.g., a toxic spill, war, or a terrorist event). In any disaster, the lives of the victims, their families, the affected community, and even the entire nation are affected in incalculable ways.

Think back to **Kara Greenwood**, the adolescent described in the beginning of the chapter. Her statement revealed her peer group's awareness of terrorism. Kara would need to obtain additional information about terrorism from community sources when preparing the discussion.

Based on national and world events, the efforts of government facilities, nongovernmental facilities, the private sector, communities, and individuals are all vital components of health and emergency response systems when a disaster occurs. In addition, accreditation bodies such as The Joint Commission (2022a) have contributed to the considerable progress that hospitals have made in disaster preparedness (U.S. Department of Health and Human Services, Office of Disease Prevention and Health Promotion, 2022). Disaster training is now more rigorous and standardized, and it encompasses the entire community and its resources. These health care coalitions provide the foundation for improved response capacity.

The National Disaster Medical System (NDMS) coordinates health care practitioners who supplement local disaster responses in large-scale disasters. In collaboration with USDHHS, Homeland Security, Veterans Affairs, and the Defense Department, they supply funds, equipment, training, and medical and support personnel (U.S. Department of Health and Human Services, 2019). Nurses have a critical role in caring for victims of a disaster.

The CDC is also committed to responding rapidly to mass trauma events and chemical, biologic, radiologic, and nuclear agents. The CDC's Health Alert Network (HAN), available at http://emergency.cdc.gov/han, has improved the ability of state and local health facilities to detect and communicate varying health threats (CDC, 2020b). The CDC has also collaborated with pharmaceutical companies and other partners to create regional stockpiles of the drugs that would be needed to treat manmade outbreaks of disease, such as anthrax, plague, and other diseases. It is dangerous for the United States to not continue to develop the optimal emergency preparedness capabilities that it needs to protect its communities. As we have seen with previous disasters, older Americans are particularly vulnerable. The age-85-years-and-older population is the fastest-growing segment of older adults, and they are at high risk during a disaster. Deficits in strength and mobility, vision and hearing loss, multiple chronic illnesses, and possible dependence on life-saving equipment make it challenging to meet their many needs (CDC, 2019a).

Addressing Biologic Threats

Bioterrorism involves the deliberate spread of pathogenic organisms into a community to cause widespread illness, fear, and panic (CDC, 2018b). The organisms used in a mass attack may not be routine, and the clinical manifestations may be vague and nonspecific. Table 28-2 (on page 866) outlines some of the more common biologic agents, including symptoms and interventions. If an unusual number of people suddenly experience similar signs and symptoms, health care personnel should consider whether they may have been exposed to a biologic agent.

Table 28-2 Biologic Agents of Concern

AGENTS	CLINICAL MANIFESTATIONS	TREATMENT/PROTECTION

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Anthrax (*Bacillus anthrax*)	Symptoms variable based on form of anthrax: • Cutaneous: Skin lesion with local edema that progresses, enlarges, ulcerates, and becomes necrotic • Gastrointestinal: Nausea, vomiting, fever, abdominal pain, hematemesis, severe diarrhea • Inhalational: Fever, fatigue, cough, dyspnea, pain; may progress to meningitis, septicemia, shock, and death	Standard precautions Decontamination possibly required for recent exposure Rapid administration of antimicrobial therapy Supportive therapy for shock, fluid volume deficit, and airway management Vaccine available; currently recommended only for high-risk populations
Botulism (*Clostridium botulinum*)	Possible release via airborne method, or contaminated food supplies Ocular symptoms such as blurred vision Skeletal muscle paralysis that progresses symmetrically and in a descending manner Muscle weakness that can result abruptly in respiratory failure	Standard precautions Passive immunization with botulinum antitoxin Supportive respiratory care
Brucellosis	Acute or insidious onset of fever and one or more of the following: night sweats, arthralgia, headache, fatigue, anorexia, myalgia, weight loss, arthritis/spondylitis, meningitis, or focal organ involvement (endocarditis, orchitis/epididymitis, hepatomegaly, splenomegaly)	PPE Supportive care Multidrug antimicrobial regimens
Plague or “black death” (*Yersinia pestis*)	Expected attack most likely airborne (inhalation of bacilli) with sudden appearance in ED of multiple patients with respiratory symptoms Symptoms similar to a severe respiratory infection Progresses rapidly to severe pneumonia, sepsis, and death	Standard precautions with droplet precautions until 48 hours after initiation of antibiotic therapy Antibiotic of choice: streptomycin (IM) or gentamicin sulfate (IM or IV); possible use of oral antibiotics (effective when mass numbers of people are ill) Fatality rate of 100% for those not receiving treatment within 24 hours of onset of symptoms
Smallpox (*Variola major,* viral agent)	Spread via direct contact or inhalation of respiratory droplets; most likely to be spread via aerosol route Flulike symptoms Characteristic rash that progresses to crusted scabs in 5 days, most prominent on face and extremities	Strict contact and airborne precautions for duration of illness—vaccination for those exposed No proven treatment Supportive care including possible antibiotics if secondary infections develop Use of antiviral agents under investigation Vaccine available; currently recommended only for high-risk populations

Tularemia (*Francisella tularensis*)	Transmission via contaminated water, food, and soil; most likely aerosolization of bacteria for use as a biologic weapon Fever Nonproductive or productive cough Possible progression to respiratory failure	Standard precautions Drug therapy such as streptomycin or gentamicin sulfate Fluid and respiratory support measures Vaccine under investigation
Viral hemorrhagic fevers (e.g., Lassa, Ebola, Marburg, yellow, and dengue fevers)	Possible spread via aerosol infection Fever Myalgias Conjunctival symptoms Mild hypotension Petechial hemorrhages Progresses to shock and hemorrhage	Standard, droplet, and contact precautions for the duration of illness; additional precautions, including use of negative-pressure room, N95, or higher respirator Use of personal protective equipment (PPE) (see Chapter 24) No proven treatment other than supportive care Avoidance of aspirin or other anticlotting drugs

Source: Adapted from Centers for Disease Control and Prevention (CDC). (2017, August 2). *Emergency preparedness and response: Bioterrorism*. https://emergency.cdc.gov/bioterrorism/

Health care personnel must adhere to the Standard Precautions recommended by the CDC. For certain diseases, additional safeguards may be necessary. If a contagious disease is suspected, the patient should be isolated accordingly. Although not usually required with biologic agents, decontamination may be necessary if a patient's exposure status is uncertain. The patient may need to bathe or shower with soap and place their clothing in sealed plastic bags. The CDC routinely posts a list of nationally notifiable conditions that include infectious diseases, noninfective conditions, and outbreaks of immediate concern (CDC, 2020a).

Addressing Chemical Threats

The use of chemical agents as a terrorist weapon is a growing concern. A **chemical emergency** could be triggered by the deliberate or unintentional release of a chemical compound that has the potential for harming people's health (CDC, 2018a). The chemical would probably be dispersed in an enclosed space, such as a subway or a closed sports arena, to cause the maximum effect. Chemical agents act rapidly, and immediate decontamination is crucial before patients are transported to a hospital. Emergency preparedness requires the swift transfer of portable decontamination units, equipment, and trained personnel to the site of the chemical attack.

Several categories of chemicals can be used as weapons of mass destruction (CDC, 2018a):

- **Biotoxins**—poisons from plants or animals
- **Blister agents/vesicants**—chemicals that severely blister the eyes, respiratory tract, and skin on contact
- **Blood agents**—poisons that are absorbed into the blood
- **Caustics (acids)**—chemicals that burn or corrode the skin, eyes, and mucous membranes on contact
- **Choking/lung/pulmonary agents**—chemicals that cause severe irritation or swelling of the respiratory tract
- **Incapacitating agents**—drugs that affect the ability to think clearly or that cause an altered state of consciousness or even unconsciousness
- **Long-acting anticoagulants**—poisons that cause bleeding by preventing blood from clotting properly
- **Metals**—agents that consist of metallic poisons
- **Nerve agents**—highly poisonous chemicals that prevent the nervous system from working properly
- **Organic solvents**—agents that damage the tissues by dissolving fats and oils
- **Riot control agents/tear gas**—highly irritating agents normally used by law enforcement for crowd control or by individual people for protection
- **Toxic alcohols**—poisonous alcohols that can damage the heart, kidneys, and nervous system
- **Vomiting agents**—chemicals that cause nausea and vomiting

Addressing Radiation Threats

Nuclear terrorism involves intentional introduction of radioactive materials into the environment for the purpose of causing injury and death. Nuclear terrorism is the most immediate and extreme threat to our global security (U.S. Department of Homeland Security, 2019). The attack might involve use of a radiation dispersion device (*dirty bomb*), a

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

planned assault at a nuclear power station or weapons facility, or dispersal of radioactive material into the food or water supply. Even a small amount of radioactive material can have devastating effects.

Radiation burns occur as a result of exposure to a radioactive source. The severity of injury depends on a variety of factors, including the duration of the exposure and the distance between the source and the person. A higher dose increases the likelihood of developing later effects such as bone marrow depression and cancer. Lymph tissue and bone marrow are the tissues most sensitive to radiation while the skin, kidneys, intestines, and gonads are the most radiation-sensitive organs (CDC, 2020f). Although the likelihood of a nuclear attack may be small, nurses need to be well informed, familiar with their facility's emergency response plan, and prepared to deal with a nuclear emergency.

Nurses serving on a radiologic emergency response team must protect themselves and wear the necessary equipment, including a radiation detection device. They will assess patients in a radiation emergency area (REA) designated by the hospital's emergency response plan. If patients have not been decontaminated at the scene of the attack, decontamination will occur at the medical facility.

Addressing Cyber Terror

Cyber terror involves the use of high technology to disable or delete critical infrastructure data or information. It is a serious threat to national security and very difficult to identify a perpetrator who resides in cyberspace. Cyberspace is particularly difficult to secure due to many factors including: (1) the ability of perpetrators to operate from anywhere in the world; (2) the linkages between cyberspace and physical systems, especially those involving critical infrastructure; and (3) and the difficulty of reducing vulnerabilities and minimizing consequences in complex cyber networks (U.S. Department of Homeland Security, 2020). The federal facilities responsible for investigating cyber terror must remain vigilant because it is difficult to predict such attacks. Authorities agree that strengthening the resilience and security of cyberspace has emerged as an important concern for national security (U.S. Department of Homeland Security, 2020). These criminals are constantly searching for vulnerabilities and looking for opportunities to launch an attack. Intruders can break into supposedly secure systems to alter files and steal confidential information. An attack on a hospital network could potentially compromise the ability of providers and nurses to care for patients and respond to health care emergencies, which could directly impact on patient safety.

Cybersecurity awareness needs to be part of the conversation with patients, families, communities, and community partners. A federally supported toolkit, updated annually, provides key messaging, engagement ideas, resources, and information on social media. The overarching theme for 2019 of "OWN IT. SECURE IT. PROTECT IT." (National Initiative for Cybersecurity Careers and Studies, n.d.) provides the framework for specific actions involving understanding, securing, and maintaining your digital profile. Internet use continues to grow in the United States and is currently at 95% or 310 million users as of January 2019. Globally there was a 75% growth between 2014 and 2019, and there are currently more than 4.39 billion global Internet users (Kemp, 2019). On average, individuals are online more than 6.5 hours every day, with some users accessing their devices hundreds of times each day. The three most popular sites are Google, YouTube, and Facebook, with Twitter losing ground and e-commerce (online shopping) steadily rising (Kemp, 2019). Gaming online and systems that support massively multiplayer online role-playing games (MMORPGs) are changing the way people socialize worldwide. The open access enjoyed by individuals comes with some responsibilities. Nurses can focus on the physical risks of increased screen time, the impact of social media on interpersonal relationships, the advantages and disadvantages of access and smart devices, the socioeconomic and generational barriers to access, the need to develop media literacy to vet sites and posts for accuracy and authenticity, and the ramifications of the globalization of communication on individual communities.

Preparing for Mass Trauma Terrorism

Terrorists have used bombs and other explosives in a variety of ways (e.g., roadside devices, on public transportation) to inflict mass trauma injuries and cause multiple fatalities. Proximity to the detonation determines the severity of injuries and mortality rates. Blast lung injury (BLI) has recently been recognized as a direct consequence of the blast wave from a high explosive detonation. Once the condition is diagnosed, the patient may require complex care and should be admitted to an intensive care unit. Key signs include a low blood pressure (hypotension), a slow heartbeat (bradycardia), and temporary pause in breathing (apnea). Few emergency health care providers in the United States have experience treating patients with explosion-related injuries.

Technology Alert

To address this lack of experience with explosion-related injuries, the CDC funded a grant for an online curriculum to address *Bombings: Injury Patterns and Care* that can be found at https://www.acep.org/imports/clinical-and-practice-management/resources/ems-and-disaster-preparedness/disaster-preparedness-grant-projects/bombings-injury-patterns-and-care/ (American College of Emergency Physicians, 2020). The CDC also released a mobile application specifically to provide immediate access to key information for providers. Download the app at https://apps.apple.com/au/app/cdc-blast-injury/id890434999?ign-mpt=uo%3D2.

Pandemic Preparation

The initial draft of this chapter for the 10th edition of the textbook was written while we were in the middle of the Coronavirus (COVID-19) pandemic and associated quarantine in the United States. I am choosing to *break the "fourth wall"* and tell you this because this is a unique situation that the average person did not expect, and it is taking a toll on people worldwide. Nurses talk about *tolerance of ambiguity*, *mindfulness*, and *resilience*—these words are part of our vernacular and things we intentionally build in response to the (ethical) stresses inherent in our work. What is striking is that because of the pandemic, the public experienced compassion fatigue and moral fatigue right along with health care providers. This pandemic has brought to light the importance of collaboration and coordination between: (1) individuals and their communities, the social contract of wearing masks; (2) individuals and their states, guidance that is geographically based; (3) states and public health experts, guidance based on data trends germane to the area; (4) states and national government, resource allocation and sharing; (5) government writ large and scientists, the CDC and the WHO are good examples; and (6) our nation and the global world—economic-, resource-, and science-based decision making. Response time, resource allocation (appropriate equipment and re-shuffling of health care providers), crisis plans (based on trends and available resources), economic impact (from unemployment to global trade), and public safety (especially of vulnerable populations) all affect decisions made by leaders and individuals. In 2019 and 2020, the intention of a united, measured response was complicated by the evolving science, the related ever-changing guidance, and inaccurate and confusing data reports. Crisis planning in moments of uncertainty is not ideal. It is far better to have a general plan in place with contingencies; funding for contact tracing and testing earmarked; resources stockpiled with production/trade agreements drafted; and a means for clear, cogent, concise dissemination of information to the public. Nurses need to lead the way in an evaluation of our collective response to the pandemic and work to shape the plan for the next global challenge.

Identifying Disaster Resources

Each health care facility should determine in advance how to deliver care should an emergency or disaster occur. This involves collaboration with internal committees and external facilities. Organizations that serve as resources for recommendations and updated information are listed in Table 28-3.

In any disaster, nurses will have multiple roles. In addition to clinical expertise, nurses may be responsible for triage, various treatments, counseling, and assistance with distribution of resources. There are many unresolved issues regarding the legal, ethical, and personal responsibilities of a nurse when a disaster occurs. There may be concerns about personal safety, legal implications, and the ethical decisions they may be called on to make in a disaster. The ANA is partnering with government facilities, employers, and individual nurses to resolve these issues and allow nurses to respond confidently with their usual compassionate attitude (American Nurses Association, n.d.c). Nurses came face-to-face with difficult decisions, challenging training, and the need to remain adaptable and flexible with evolving protocols and policies in the Ebola crisis and in the Coronavirus (COVID-19) pandemic. The ANA Enterprise created an online COVID-19 Resource Center that includes clinical information, legislative and regulatory advocacy information, licensure information, ethical considerations, other nurse-specific resources (American Nurses Association, n.d.a). These experiences provided nurses the opportunity to engage in the creation of plans and strategies for the proper management of future epidemics and mass disaster situations.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Staying Abreast of the Science During a Pandemic

Evolving science, the availability of massive amounts of un-vetted information through nontraditional dissemination mediums (e.g., social media), varied levels of health literacy, ineffective and misleading communication, and other factors have forced health care providers to educate and make decisions in a tense environment. The application of best evidence requires the ability to locate, appraise, synthesize, and articulate findings of scientific research. Nurses routinely stay abreast of new developments and integrate current guidelines and principles into their delivery of nursing care. A change in nursing practice is typically based on peer-reviewed research that informs facility-based guidelines, protocols, and policies. The sheer volume of information available to nurses in their personal and professional lives, and the speed with which this information is accessible, challenges nurses to identify reliable sources of information.

Related Research

Science brief: COVID-19 vaccines and vaccination. (2021). In National Center for Immunization and Respiratory Diseases (NCIRD), Division of Viral Diseases, *CDC COVID-19 Science Briefs*. Centers for Disease Control and Prevention (US). https://www.ncbi.nlm.nih.gov/books/NBK570435/

The CDC routinely disseminates a summary of recent changes to document the current state of vaccination and provide up-to-date recommendations. Although previous science briefs addressed the efficacy of vaccination in general, this report from September 15, 2021 reiterates the efficacy of vaccination against COVID-19 hospitalization

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and death caused by the biggest, current issue, the Delta variant of SARS-CoV-2. The brief integrates new data from studies published since the last update regarding the benefit of a third dose of vaccine in specific populations, mixed vaccine schedules, duration of protection from vaccination, and clinical transmissibility in fully vaccinated persons. To explain the scope of this work, the International Vaccine Access Center, Johns Hopkins Bloomberg School of Public Health and World Health Organization publish weekly summary tables that contribute to their ongoing systematic review of the results of students on COVID-19 vaccination effectiveness (https://view-hub.org/resources). Their October 14, 2021, systematic review table contained 105 studies regarding post-authorization COVID-19 vaccine effectiveness that met inclusion criteria. They also identified 133 studies that may be of interest but did not meet inclusion criteria. This is just one of the myriad resources that inform the CDC's science briefs and guidance documents for vaccination and for fully vaccinated people.

Relevance to Nursing Practice

It is important that nurses reflect on lesson learned during the pandemic and use that information to inform the collective response to future issues. Although staying abreast of developments is important for all health care providers, independently completing an ongoing systematic review and analysis of an evolving pandemic is unrealistic. Best practice involves leveraging expert synthesis and analysis to inform decision making and drive the creation of up-to-date guidance at the facility and national levels.

Table 28-3 Emergency Preparedness Resources

ORGANIZATION	ACTIVITIES
National Disaster Medical System (NDMS) http://www.phe.gov/Preparedness/responders/ndms/Pages/default.aspx	Has responsibility for managing and coordinating the federal medical response to major emergencies and federally declared disasters
Federal Emergency Management Agency (FEMA) http://www.fema.gov	Works to build and support the national emergency management system
Centers for Disease Control and Prevention (CDC) http://www.cdc.gov	Acts as the lead federal facility for disease prevention and control activities; provides backup support to state and local health departments
The Joint Commission http://www.jointcommission.org	Accredits facilities according to established safety and quality standards; revises the emergency management standards for health care facilities
American Red Cross http://www.redcross.org	Acts as the lead nongovernmental facility that provides safety information and disaster response
Department of Homeland Security http://www.dhs.gov/index.shtm	Protects the nation against further terrorist attacks and coordinates the response for future emergencies

Disaster preparedness is imperative at all levels. In order to reduce confusion and lessen the impact of a disaster, people need to take responsibility, include the family in all discussions, and develop a personal disaster plan. The American Red Cross (2022) recommends a very straightforward plan of action for emergency preparedness: get a kit, make a plan, and be informed. Emergency food, supplies, and medications should be assembled; a communication routine should be established, and sources for reliable information should be monitored when disaster strikes. Multiple resources are available to assist in this preparation including one from the CDC (http://emergency.cdc.gov/preparedness).

Addressing Psychological Aspects of Disasters

Disasters affect the lives of victims, family members, and health care personnel in many ways. Fear and panic can be expected. Other potential emotions include anger, horror, as well as real and exaggerated concerns about possible future events. Nurses and other health care providers (as first responders), rescue and recovery workers, and staff at a medical facility, can help to minimize panic by addressing risks and providing careful explanations. Anxiety and moral fatigue can be addressed with reassurance and emotional support. The impact of a disaster on each person varies, and it can have lingering effects. Most disaster survivors experience normal stress reactions, but some may exhibit acute stress disorder or posttraumatic stress disorders that require treatment. Emergency preparedness education and planning must also address mental health issues.

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the object of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop your expertise in evaluating the plan of care, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following:

- How aware are you of the developmental considerations regarding safety? Are you able to articulate them and teach at the appropriate level?
- What value do you attach to involving the patient in safety and security? How do you individualize the care for patients when so many guidelines, policies, and procedures dictate your care?
- How can nurses impact change at the system and population levels? What is the role of the nurse in health care and population- or community-based initiatives? How do you see nurses' agency manifest in these situations?
- What plan do you have to stay abreast of evolving statistics on national issues? How do you plan to be aware of current global security issues and the associated recommendations at the facility, local, state, national, and global levels?

Keeping up with the latest evidence-based practice guidelines can be challenging. Global shifts and evolving statistics change the emphasis of our nursing care. Balancing the needs of your individual patient with these responsibilities requires mindfulness and intentionality.

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to ensure appropriate safety and security practices? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Skill 28-1 Performing a Situational Assessment

DELEGATION CONSIDERATIONS

A situational assessment should not be delegated to assistive personnel (AP). However, the AP may notice some items while providing care. The nurse must then validate, analyze, document, communicate, and act on these findings, as appropriate. Depending on the state's nurse practice act and the organization's policies and procedures, the licensed practical/vocational nurses (LPN/LVNs) may perform some or all of the parts of a situational assessment. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
 1. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 2. Identify the patient. Explain the purpose of the assessment to the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors. Explanation helps reduce anxiety and promotes engagement and understanding.
3. Assess for data that suggest a problem with the patient's airway, breathing, or circulation. If a problem is present, identify if it is urgent or nonurgent in nature. Refer to Chapter 27 for specific related assessments.	Problems with the patient's airway, breathing, or circulation may signal a situation requiring immediate action. It is important to determine the importance of information, focus on the most relevant and important data, act on that which is important and develop plans for interventions that can be justified in relation to their likelihood of success (Lasater, 2007).
4. Assess the patient's level of consciousness, orientation, and speech. Observe the patient's behavior and affect (Figure 1). If a problem is present, identify if it is urgent or nonurgent in nature. Refer to Chapter 27 for specific related assessments.	Problems with the patient's level of consciousness, orientation, speech, behavior, or affect may signal a situation requiring immediate action. It is important to determine the importance of information, focus on the most relevant and important data, act on that which is important and develop plans for interventions that can be justified in relation to their likelihood of success (Lasater, 2007).

FIGURE 1. Observing the patient's behavior and affect. (*Source:* Used with permission from Shutterstock. *Photo by Rick Brady.*)

5. Assess the patency of an oxygen delivery device, if in use. Refer to Chapter 40 for specific related assessments.	Properly functioning equipment is required to maintain delivery of oxygen.
6. Assess other relevant *priority* body systems as appropriate, based on individual patient circumstances.	Nurses must use clinical judgment to adapt this assessment for each patient, based on the individual circumstances of an individual patient (Henley Haugh, 2015).
7. Survey the patient's environment. Assess the bed position and call bell location. The bed should be in the lowest position, and the call bell (based on specific patient care setting) should be within the patient's reach.	Environmental survey identifies problems that may harm the patient (Cohen, 2013).
8. Assess for clutter and hazards. Remove excess equipment, supplies, furniture, and other objects from rooms and walkways. Pay particular attention to high traffic areas and the route to the bathroom.	All are possible hazards and could cause the patient to fall.
9. Note the presence and location of appropriate emergency equipment, based on individual patient situation.	Emergency equipment must be immediately available if needed.
10. Note the presence and location of appropriate assistive devices and mobility aids, based on individual patient situation. Ensure any devices are within the patient's reach.	Assistive devices should be available for patient use.
11. Assess for the presence of an intravenous (IV) access and/or infusion. Assess patency of the device and the insertion site. If an infusion is present, assess the solution and rate. Refer to Chapter 41 for specific related assessments.	Assessment allows for identification of problems and ensures administration of intravenous fluids as prescribed.
12. Assess for the presence of any tubes, such as gastric tubes, chest tubes, surgical drains, or urinary catheters. Assess patency of the device and insertion site. Refer to Chapters 33 and 37 to 40 for specific related assessments.	Assessment allows for identification of problems and ensures patency of devices.
13. Provide a bedside commode and/or urinal/bedpan, if appropriate. Ensure that it is near the bed at all times.	This prevents falls related to incontinence or trying to get to the bathroom.
14. Ensure that the bedside table, telephone, and other personal items are within the patient's reach at all times.	This prevents the patient from having to overreach for a device or items, and/or possibly attempt ambulation or transfer unassisted.
15. Consider what further assessments should be completed and additional interventions that may be indicated. Identify problems that need to be communicated and whom to contact.	Early detection of problems allows for corresponding interventions to prevent adverse occurrences, supporting improved patient outcomes (Large & Aldridge, 2018).
 16. Remove PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.

DOCUMENTATION

Guidelines

Document significant assessment findings as directed by facility policy and protocol. Include associated interventions and/or related communication.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

SPECIAL CONSIDERATIONS

Community-Based Care Considerations

- Examine the home for objects on the floor, the presence of wires or cords, objects on the steps, and loose or torn carpet. Encourage residents to keep walkways, floors, and stairs clear.
- Assess for adequate lighting, especially at the top and bottom of stairs and pathways from the bedroom to bathroom.
- Assess for the presence of working smoke detectors at a minimum on every floor of the home, ideally in every room. Provide education regarding safe use as appropriate.
- Assess for the presence of a carbon monoxide detector.
- Assess for the presence of firearms in the home. Provide education regarding safe storage as appropriate.
- Assess for the presence of space heaters. Provide education regarding safe use as appropriate.
- If there are children in the home, evaluate the method used to store medications, cleaning products, insecticides, and corrosives. Provide education regarding safe storage as appropriate and Poison Control Center contact information.

Skill 28-2 Applying an Extremity Restraint

DELEGATION CONSIDERATIONS

After assessment of the patient by the RN, the application of an extremity restraint may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Appropriate cloth restraint for the extremity that is to be immobilized
- Padding, if necessary, for bony prominences
- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Determine the need for restraints. Assess the patient's physical condition, behavior, and mental status.	Restraints should be used only as a last resort when alternative measures have failed, and the patient is at increased risk for harming self or others.
2. Confirm facility policy for the application of restraints. **Secure an order from the physician or other licensed practitioner who is permitted to order restraint or seclusion in that health care facility, or validate that the order has been obtained within the required time frame (CMS, 2020).**	Policy protects the patient and the nurse and specifies guidelines for application as well as the type of restraint and duration. **Each order for restraint or seclusion used for the management of violent or self-destructive behavior that jeopardizes the immediate physical safety of the patient, a staff member, or others may only be renewed in accordance with the following limits for up to a total of 24 hours: (A) 4 hours for adults 18 years of age or older, (B) 2 hours for children and adolescents 9 to 17 years of age, or (C) 1 hour for children under 9 years of age. After 24 hours, before writing a new order for the use of restraint or seclusion for the management of violent or self-destructive behavior, a physician or other licensed practitioner who is permitted to order restraint or seclusion in that health care facility and responsible for the care of the patient must see and assess the patient** (CMS, 2006).
	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on

 3. Perform hand hygiene and put on PPE, if indicated.	transmission precautions.
 4. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
5. Explain the reason for restraint use to patient and family/caregivers. Clarify how care will be given and how needs will be met. Explain that restraint is a temporary measure.	Explanation to the patient and family/caregivers may lessen confusion and anger and provide reassurance. A clearly stated facility policy on the application of restraints should be available for the patient and family/caregivers to read. In a long-term care facility, the family/caregivers must give consent before a restraint is applied.
6. Include the patient's family and/or caregivers in the plan of care.	Promotes person-centered, individualized care and engagement, continuity of care and understanding.
7. Inspect the restraint before use. Do not use a restraint that is soiled or damaged (TIDI Products, 2018a).	Always inspect the device before each use, checking for broken stitches or parts, torn, cut or frayed material; or locks, buckles or hook-and-loop fasteners that do not hold securely. Do not use soiled or damaged restraints to prevent injury or death (TIDI Products, 2018a).
8. Apply restraint according to the manufacturer's directions:	Proper application reduces the risk for injury.
a. Choose the least restrictive type of device that allows the greatest possible degree of mobility.	This provides minimal restriction.
b. Pad bony prominences.	Padding helps prevent skin injury.
c. Wrap the restraint around the extremity with the soft part in contact with the skin (Figure 1). If a hand mitt is being used, pull over the hand with cushion to the palmar aspect of the hand (Figure 2).	Prevents excess pressure on the extremity.

FIGURE 1. Wrapping the restraint around the extremity with the soft part in contact with the skin.

FIGURE 2. Using a hand mitt, with cushion to the palmar aspect of hand.

9. Secure in place with the hook-and-loop fastener straps or other mechanism, depending on specific restraint device (Figure 3). Depending on the characteristics of the specific restraint, close the quick-release buckle on the cuff.	Proper application secures the restraint and ensures that there is no interference with the patient's circulation and potential alteration in neurovascular status.
10. **Ensure that one to two fingers can be inserted between the restraint and patient's extremity (Figure 4).**	The restraint must be snug, but not compromise circulation (TIDI Products, 2018b). Proper application ensures that nothing interferes with the patient's circulation and potential alteration in the neurovascular status.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 3. Securing restraint on extremity.

FIGURE 4. Ensuring that two fingers can be inserted between the restraint and the patient's extremity.

11. Maintain restrained extremity in normal anatomic position. **Use a quick-release knot to tie the restraint to the bed frame that moves with the patient, not side rail, bed rail, mattress, or head/footboard (Figure 5).** The restraint may also be attached to a chair frame. The site should not be readily accessible to the patient.

Maintaining a normal position lessens the possibility of an injury. A quick-release knot ensures that the restraint will not tighten when pulled and can be removed quickly in an emergency. Securing the restraint to a side rail may injure the patient when the side rail is lowered. Tying the restraint out of the patient's reach promotes security.

FIGURE 5. Securing restraint to bed frame.

12. Remove PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.

13. **Assess the patient according to facility policy, or more often, based on the individual patient circumstances and nursing judgment.** Assessment should include the placement of the restraint, neurovascular assessment of the affected extremity, and skin integrity. In addition, assess for signs of sensory deprivation, such as increased sleeping, daydreaming, anxiety, panic, and hallucinations. Monitor the patient's vital signs.

The condition of the restrained patient must be continually assessed, monitored, and reevaluated (CMS, 2006). The frequency of monitoring should be made on an individual basis, which includes a rationale that reflects consideration of the individual patient's medical needs and health status (CMS, 2006). Improperly applied restraints may cause skin tears, abrasions, or bruises. Decreased circulation may result in paleness, coolness, decreased sensation, tingling, numbness, or pain in extremity. The use of restraints may decrease environmental stimulation and result in sensory deprivation. Monitoring vital signs provides information about the status of the patient.

14. **Remove restraint at least every 2 hours or according to facility policy, individual patient circumstances, and nursing judgment. Remove**

Removal allows you to assess the patient and reevaluate the need for a restraint. It also allows interventions for toileting, provision of nutrition and liquids,

the restraint at least every 2 hours for children 9 to 17 years of age and at least every 1 hour for children under 9 years of age, or according to facility policy, individual patient circumstances, and nursing judgment. Perform range-of-motion (ROM) exercises. Provide for hydration, nutritional, and elimination needs.	exercise, and change of position. Exercise increases circulation in the restrained extremity.
15. **Evaluate the patient for continued need of restraint.** Reapply restraint only if continued need is evident and order is still valid.	Continued need must be documented for reapplication.
16. Reassure the patient at regular intervals. Provide continued explanation of rationale for interventions, reorientation if necessary, and plan of care. **Keep the call bell within the patient's easy reach.**	Reassurance demonstrates caring and provides an opportunity for sensory stimulation as well as ongoing assessment and evaluation. The patient can use the call bell to summon assistance quickly.

Documentation

Guidelines

Document alternative measures attempted before application of the restraint and that less restrictive interventions have been determined to be ineffective. Document patient assessment before application. Record patient and family/caregiver education and understanding regarding restraint use. Document family/caregiver consent, if necessary, according to facility policy. Document reason for restraining patient, date and time of application, type of restraint, times when removed, and frequency and result of nursing assessments.

Sample Documentation

7/10/25 0830 Patient disoriented and combative. Attempting to remove tracheostomy and indwelling urinary catheter; verified with primary physician both devices are necessary at this time. Patient continued to tug at catheter and pull on tracheostomy while supervised at bedside. Family unwilling to sit with patient. Wrist restraints applied bilaterally as prescribed.

—K. Urhahn, RN

7/10/25 1030 Patient continues to be disoriented and combative. Wrist restraints removed for 30 minutes during patient's bath; skin intact, hands warm, even skin tone, +radial pulses, +movement; passive and active range of motion completed. Wrist restraints reapplied.

—K. Urhahn, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient has an IV catheter in the right wrist and is trying to remove a drain from a wound:* The left wrist may have a cloth restraint applied. Due to the IV in the right wrist, alternative forms of restraints could be tried, such as a cloth mitt or an elbow restraint.
- *Patient cannot move left arm:* Do not apply the restraint to an extremity that is immobile. If the patient cannot move the extremity, there is no need to apply a restraint. Restraint may be applied to right arm after obtaining an order from the physician or other licensed practitioner who is permitted to order restraint or seclusion in that health care facility and is responsible for the care of the patient.

SPECIAL CONSIDERATIONS

General Considerations

- Do not position patient with wrist restraints flat in a supine position due to an increased risk for aspiration (Springer, 2015). If supine position is necessary, be aware that constant monitoring may be required to reduce risk for complications for those at risk of vomiting while restrained (TIDI Products, 2018a).
- Check restraint for correct size before applying. Extremity restraints are available in different sizes. If restraint is too large, patient may free the extremity. If restraint is too small, circulation may be affected.
- Avoid use on an extremity restraint on a limb with a dislocation or fracture (TIDI Products, 2018b).
- Do not use on an extremity with an IV or wound site that could be compromised by the device (TIDI Products,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

2018b).

- Always inspect the device before each use, checking for broken stitches or parts, torn, cut or frayed material; or locks, buckles or hook-and-loop fasteners that do not hold securely. Do not use soiled or damaged restraints (TIDI Products, 2018a).

Community-Based Care Considerations

- In long-term care facilities, patients have the right to be free from physical or chemical restraint not required to treat the resident's medical symptoms. When the use of restraints is indicated, the facility must use the least restrictive alternative for the least amount of time and document ongoing re-evaluation of the need for restraints (2020b).

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. You are the visiting nurse for a frail older adult who lives alone in her own home and prizes her independence. You assess her to be at high risk for falls because of her general weakness, the medication she takes, and a long history of indifference to safety counseling. What instruments can you use to determine her falls risk? What is the benefit of using a standardized instrument/tool for risk assessment? What nursing interventions are likely to be most effective in ensuring her safety?

. You are the nurse lobbying for improvement in state and federal emergency preparedness. What do you see as your top three priorities? Which federal agencies would be the best partners? What state and community resources should be considered? Why is emergency preparedness so important?

PRACTICING FOR NCLEX

. The nurse manager and nurses in an acute care hospital are participating in a safety huddle to identify patients at risk for falling. Which patients will the nurses determine require follow-up? Select all that apply.

a. Age >50 years
b. History of falling
c. Taking antibiotics
d. Presence of postural hypotension
e. Nausea from chemotherapy
f. Transferred from long-term care

. A school nurse is teaching parents about home and fire safety. What information will be included in the teaching plan? Select all that apply.

a. Sixty percent of U.S. fire deaths occur in the home.
b. Most fatal fires occur when people are cooking.
c. Most people who die in fires die of smoke inhalation.
d. Fire-related injury and death have declined due to the availability and use of smoke alarms.
e. Fires are more likely to occur in homes without electricity or gas.
f. Fires are less likely to spread if bedroom doors are kept open when sleeping.

. A community health nurse is providing education on child safety. Who does the nurse identify as at highest risk for choking and suffocation?

a. A toddler playing with his older brother's wooden blocks
b. A 4-year-old eating yogurt and strawberries for lunch
c. An infant sleeping in the prone position
d. A 3-year-old drinking a glass of juice

. While discussing home safety with the nurse, a patient admits that they smoke a cigarette in bed before falling asleep at night. Which health problem is the priority for this patient?

a. Impaired gas exchange: etiology, cigarette smoking
b. Acute anxiety: etiology, inability to stop smoking
c. Nonadherence: etiology, nonadherence to recommendation to stop smoking
d. Knowledge deficiency: etiology, risk for burn and suffocation in a house fire

. A nurse working in a pediatrician's office receives calls from parents whose children have ingested a toxic substance from under the sink. How will the nurse advise the parents?

a. Administer activated charcoal in tablet form and take child to the ED.
b. Administer syrup of ipecac and take child to the ED.
c. Bring the child in to the primary care provider for gastric lavage.

d. Call the PCC immediately before attempting any home remedy.

. A nurse is teaching parents in a parenting class about the use of car seats and restraints for infants and children. What should be the focus of this education?

a. Booster seats should be used for children until they are 4′9″ tall and weigh between 80 and 100 lb.
b. Most U.S. states mandate the use of infant car seats and carriers when transporting a child in a motor vehicle.
c. Infants and toddlers up to age 2 years (or the maximum height and weight for the seat) should be in a front-facing safety seat.
d. Children age older than 6 years may be restrained using a car seat belt in the back seat.

. A nurse in a long-term care facility is on an interprofessional safety committee focusing on protecting older adults from injury and trauma. Which action does the nurse suggest they prioritize?

a. Ensuring proper function of fire alarms
b. Preventing exposure to temperature extremes
c. Screening for partner or elder abuse
d. Maintaining clutter free rooms and hallways

. An experienced nurse and new graduate nurse are caring for a confused older adult who gets out of bed and wanders. The preceptor intervenes when observing which action by the graduate nurse?

a. Raising all four side rails to keep the patient in bed
b. Performing documentation in the patient's room
c. Suggesting obtaining a patient "sitter"
d. Using a bed alarm to alert staff the patient leaving the bed

. The hospital's fire alarm sounds, and an announcement is made that there is a fire in a patient room. What is the priority for nurses on the unit?

a. Removing patients from the room or vicinity
b. Attempting to put out the fire with water or appropriate extinguishers
c. Closing all the doors on the unit to contain the fire
d. Running to the closest unit and requesting help

. A nurse is filing a safety event report for a confused patient who fell while getting out of bed. Which action is most appropriate during documentation?

a. Including suggestions on how to prevent the incident from recurring
b. Providing minimal information about the incident
c. Discussing the details with the patient before documenting them
d. Recording the circumstances and effect on the patient in the health record

. Nursing students are invited to participate in the clinical agency's annual disaster drill, simulating the release of an airborne infectious agent and ensuing panic. Which assignment is most appropriate for the students?

a. Cleansing and dressing wounds sustained during the panic
b. Triaging patients with respiratory symptoms and traumatic injuries
c. Providing information to families of missing loved ones
d. Ensuring everyone entering and working has an N95 mask

. A disoriented older resident likes to wander the halls of their long-term care facility but becomes agitated when they cannot find their room. Which action is most appropriate as an alternative to restraints?

a. Placing them in a geriatric chair near the nurses' station
b. Using the sheets to secure them snugly in the bed
c. Keeping the bed in the high position
d. Identifying their door with his photograph and a balloon

. A nurse has exhausted every effort to keep a confused, postoperative patient safe and in bed. Following The Joint Commission guidelines for use of restraints, which nursing action reflects safe practice?

a. Positioning the patient in the supine position prior to applying wrist restraints
b. Ensuring that two fingers can be inserted between the restraint and patient's wrist
c. Applying a cloth restraint to the left hand of the patient with an IV catheter in the right wrist
d. Tying an elbow restraint to the raised side rail of the patient's bed

. During the admission process, a nurse orients an older adult to their hospital room. What is the current safety priority?

a. Explaining how to use the telephone
b. Introducing the patient to their roommate

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

c. Reviewing the hospital policy on visiting hours
d. Demonstrating how to operate the call bell

. A nurse works in a facility stating they support a culture of safety. What will the nurse expect to find operationalized in this culture? Select all that apply.

a. Support for reporting errors and near misses without blame
b. Nurses being the employees responsible for safety in the organization
c. Commitment of resources to address actual/potential safety issues
d. Emphasis placed on individuals, their departments, and resources
e. Promotion of teamwork and collaboration throughout the organization
f. Administrators' and managers' commitment to safe operations

. A school nurse is teaching about adolescent safety with students entering high school. What will the nurse include in the discussion about the major causes of death in this group? Select all that apply.

a. Choking
b. Diving accidents
c. Car accidents
d. Suicide
e. Intimate partner violence
f. Cigarette smoking

ANSWERS WITH RATIONALES

. **b, d, f**. Risk factors for falls include age >65 years, documented history of falls, postural hypotension which can cause dizziness, and unfamiliar environment. A medication regimen that includes diuretics creating urinary urgency and tranquilizers, sedatives, hypnotics, or analgesics causing altered mental status and impaired judgment are also risks. Chemotherapy or antibiotics are not included as factors leading to falls.

. **c, d, e.** Eighty percent of fire deaths in the United States occur in the home. Most fatal home fires occur while people are sleeping, and most deaths result from smoke inhalation rather than burns. The widespread availability and use of home smoke alarms is considered the primary reason for the decline in fire-related injury and death. People with limited financial resources may use space or kerosene heaters, wood stoves, or a fireplace as the sole source of heat if utilities are turned off. Bedroom doors should be kept closed when sleeping and monitors used to listen for children.

. **c**. Infants should be placed on their backs to sleep. A young child may place small or loose parts in the mouth. Anything that will fit through the average toilet paper roll is not safe for a toddler. A 3-year-old and a 4-year-old drinking juice and eating yogurt are developmentally appropriate.

. **c**. Because the patient is not aware or denies that smoking in bed poses a danger for fire and toxic fumes, education about the risk for burns and suffocation is needed. The other three nursing diagnoses are correctly stated but are not a priority in this situation.

. **d**. The nurse tells the parents to call the PCC immediately, before attempting a home remedy. Parents may be instructed to bring the child to an emergency facility for immediate treatment. Activated charcoal is not appropriate to use at home but under medical supervision, after the risks and benefits have been assessed. Syrup of ipecac is no longer recommended because vomiting may exacerbate the hazard as it vomited up. Gastric lavage is no longer prescribed routinely for the treatment of ingestion of a toxic substance because it may propel the poison into the small intestine, where absorption will occur. The amount of toxin removed by gastric lavage is relatively small.

. **a**. Booster seats should be used for children until they are 4′9″ tall and weigh between 80 and 100 lb. All 50 U.S. states mandate the use of infant car seats and carriers when transporting a child in a motor vehicle. Infants and toddlers up to age 2 years (or up to the maximum height and weight for the seat) should be in a rear-facing safety seat. Many children older than age 6 years should still be in a booster seat.

. **d.** Falls among older adults are the most common cause of hospital admissions for trauma, therefore rooms and hallways should be free of clutter. Elder abuse, fires, and temperature extremes are also significant hazards for older adults but are not the most common cause of trauma admissions. IPV occurs more frequently in adults as opposed to older adults.

. **a**. The desire to prevent a patient from wandering is not sufficient reason for the use of side rails. People of small stature are more likely to be injured slipping through or between the side rails. A history of falls from a bed with raised side rails carries a significant risk for a serious incident. The nurse uses creative measures while promoting safety and respect for the patient's dignity.

. **a**. The nurse uses the acronym RACE and rescues and/or removes the patient and those in nearby rooms as the safety priority. Sounding the alarm and extinguishing the fire are important after the patient is safe. Remaining on the unit allows you to assist patients and is more appropriate; assistance can be summoned by phone.

. **d**. A safety event report objectively describes the circumstances of the accident or incident. The report also details the patient's response and the examination and treatment of the patient after the incident. The nurse completes the event report immediately after the incident and is responsible for recording the circumstances and the effect on the patient in the medical record. The safety event report is not a part of the medical record and should not be mentioned in the documentation. Because laws vary in different states, nurses must know their own state law regarding safety event reports.

. **d.** Rapid assessment and triage are essential during a disaster. Delegating tasks appropriate to students are based on skill level and ability to complete skills independently. Ensuring masks are worn and the education for this, if needed, are within the educational and clinical skills of nursing students.

. **d**. This allows the resident to be on the move and be more likely to find their room when they want to return. Many facilities use this kind of approach, rather than restrict patients' movements. Identifying the patient's door with their photo and a balloon may resolve the issue without restraints. Using the geriatric chair and sheets are forms of physical restraint. Leaving the bed in the high position is a safety risk and would likely result in a fall.

. **b**. The nurse should be able to place two fingers between the restraint and a patient's wrist or ankle. Restraining the patient in a supine position increases the risk of aspiration. Due to the IV in the right wrist, alternative forms of restraints should be tried, such as a cloth mitt or an elbow restraint. Securing the restraint to a side rail may injure the patient when the side rail is lowered.

. **d**. Teaching the patient to use the call bell is a safety priority; knowing how to use the phone, meeting the roommate, and knowledge of visiting hours will not necessarily prevent an accidental injury.

. **a, c, e, f.** The key features of a culture of safety include: (1) acknowledging the high-risk nature of health care and the commitment to safe operations, (2) maintaining a blame-free environment where reporting is protected and expected, (3) promoting teamwork and collaboration to prevent and seek solutions to patient safety issues, and (4) valuing safety as a focus in all health care facilities, the home, workplace, and community.

. **c, d.** Car accidents and suicide are common causes of death in adolescents. Choking is more typical in children younger than age 3 years. While diving accidents can occur in adolescents due to poor judgment, this is not as common. Intimate partner violence is more common in adults. Smoking, while ill advised, takes many years or decades to become a cause of death.

Complementary and Integrative Health

Brian Legett

Brian, a 30-year-old man with a long history of back problems due to a work injury, comes to the clinic for evaluation. He states, “I’ve had so many kinds of treatment, and nothing seems to work. Maybe, I should see a chiropractor?”

Sylvia Puentes

Sylvia, a middle-aged woman, is scheduled for abdominal surgery next week. She comes to the outpatient clinic for preoperative evaluation and laboratory testing and says, “I’m really anxious about the surgery, but I don’t want to take any medicines. Is there anything I can do to help me relax?”

Lee Chen

Lee, a 65-year-old man dying of lung cancer, was brought to the United States from China by his two

daughters, who believed that U.S. medicine would cure him. Mr. Chen did not respond to any of the therapies that were attempted, and the team wants to transition to palliative care. The daughters are unwilling to authorize removal of ventilatory support or sign a do-not-resuscitate order. They request an acupuncturist, but their health care provider refuses their request.

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Differentiate complementary health approaches and integrative health from allopathic/conventional medicine.
. Compare and contrast the beliefs about the origin of disease and ways to promote health of each of the three main categories of complementary health approaches.
. Describe ways in which nurses can use knowledge of complementary health approaches and integrative health in providing patient care.
. Identify the knowledge the public should possess about complementary health approaches and integrative health if they wish to be informed consumers.
. Describe ways in which nurses can use selected complementary health approaches for self-care and health promotion.

Nursing Concepts

Clinical Decision Making/Clinical Judgment
Health
Wellness
Illness

Key Terms

acupuncture
allopathic medicine
aromatherapy
Ayurveda
chiropractic health care
complementary health approaches (CHAs)
guided imagery
healing touch (HT)
holism
holistic nursing
Homeopathy
integrative health (IH)
meditation
qi gong
Shamanism
therapeutic touch (TT)
traditional Chinese medicine (TCM)

Many people in the United States are using complementary health approaches (CHAs) and integrative health (IH) care to promote health and assist with healing from illness. The term **complementary health approaches (CHAs)** refers to health care interventions that are not typically part of conventional medical care that are used together with conventional medical interventions (NCCIH, 2020a). The term **integrative health (IH)** refers to the combination of complementary health and conventional health approaches in a coordinated way (NCCIH, 2020a). If a nonmainstream practice is used in place of conventional medical care, it is considered an alternative modality. However, most people who use health care approaches that are not typically part of conventional medical care also use conventional health care (NCCIH, 2020a) and therefore alternative care will not be discussed in this chapter. The term *complementary and alternative medicine*

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

(CAM) is also still sometimes used; however, this terms does not accurately reflect the fact that CHAs and IH care are not "medicines" and people without medical degrees practice CHAs/IH. This chapter discusses basic CHA and IH concepts that a practicing nurse needs to understand to provide safe nursing care.

Nurses need to be knowledgeable about CHAs for several reasons. The World Health Organization's definition of health identifies, "Health is a complete physical, mental and social well-being and not merely the absence of disease or infirmity" (WHO, n.d., para 1). Health and illness are affected by all components of an individual, including their body, mind and spirit and efforts to promote health and treat illness benefit from an integration of conventional Western medicine with complementary and alternative therapies (Eliopoulos, 2018a). The use of integrative approaches to health and wellness has grown within care settings across the United States (NCCIH, 2020a, para 8). Consumers increasingly desire and are using care options beyond conventional medicine (Eliopoulos, 2018a) and patients, families, other health care providers, and health care institutions increasingly expect practicing nurses to be knowledgeable about CHA. Patients may use these types of therapies as outpatients and want to continue their use as inpatients. They or family members/caregivers may expect nurses to administer herbal preparations or nutritional supplements or ask advice regarding the use of these therapies. Also, it is not uncommon for people to retain health care practices brought from other countries although they reside in the United States. In these situations, nurses can assist patients by accommodating CHA/IH healing practices as much as possible. In addition, as evidence grows demonstrating the effectiveness of selected CHAs, many institutions now provide complementary therapies to inpatients as part of total patient care in an effort to provide IH care. Refer to the accompanying Reflective Practice display box on page 884.

Another reason nurses need to be knowledgeable about CHAs is that many nurses are expanding their clinical practice by incorporating CHAs. Many state boards of nursing recognize select complementary modalities as part of nursing practice and have provisions for the safe practice of these modalities by registered nurses.

Finally, although CHAs may seem totally safe, some therapies have led to harmful and, at times, potentially lethal outcomes. Nurses play an important role in educating the public about how these therapies can be used safely and effectively. This chapter will provide helpful resources for education.

QSEN PATIENT-CENTERED CARE

It is important for the nurse to recognize and consider personally held attitudes and beliefs regarding complementary and integrative health approaches and not allow personal values to interfere with the provision of individualized care that respects individual patient values, preferences, and expressed needs.

INTRODUCTION TO COMPLEMENTARY HEALTH APPROACHES

Although the use of most CHAs predates modern medicine, it was not until recently that nursing and medical schools began to teach about their use. The sharp divide between conventional Western medicine and CHAs has now softened, and successful practitioners know how to combine the two successfully.

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO COGNITIVE SKILLS

This spring, while working on an oncology floor, I was caring for Lee Chen, a 65-year-old man dying of lung cancer. His two daughters, who were living in the United States, had brought him from China to the United States, believing that U.S. medicine would cure him. Unfortunately, Mr. Chen's cancer had not responded to any of the therapies that were attempted. All of his professional caregivers believed that the goal of treatment should now be preparation for a comfortable and dignified death using compassionate palliative care. His daughters, however, were unwilling to accept this goal and would not authorize removing him from ventilatory support or issuing a do-not-resuscitate order. Mr. Chen could no longer speak on his own behalf. One afternoon, one of his daughters informed Mr. Chen's health care provider that she was going to bring an acupuncturist in to work on her father. The health care provider told her in no uncertain terms that he would not allow "voodoo medicine" on his unit. I wasn't sure what to do because both daughters were growing more and more upset, and this answer seemed like the "last straw."

Thinking Outside the Box: Possible Courses of Action

- Accept the status quo and try to comfort the daughters.
- Support the health care provider's judgment and try to get the daughters to see things his way.
- Learn more about acupuncture and related benefits and harms (I have never seen it done and know very little about what to expect).

- Find out if the health care provider really had the authority to forbid acupuncture on this patient.
- Advocate for the patient and his family if there is a possibility that acupuncture will benefit him.

Evaluating a Good Outcome: How Do I Define Success?

- Patient receives culturally appropriate, thoughtful person-centered care consistent with the goals of compassionate palliative care.
- The patient is not harmed.
- Mr. Chen's daughters feel supported as they struggle with decisions and anticipatory grieving.
- All health care team members (including Mr. Chen's health care provider) learn about acupuncture and other CHAs, as well as about the hospital's policies regarding their use.
- The health care provider is confronted in a professional manner about the behavior, as it increased stress on the family caregivers.
- I grow in my knowledge of how to incorporate CHA into my care.

Personal Learning: Here's to the Future!

I was so upset by the daughters' distress that I decided to learn more about acupuncture. After searching the Internet and talking with a nurse who was receiving acupuncture treatments, I decided that acupuncture treatments were unlikely to harm the patient; in fact, the treatments just might help to increase his comfort level. At the very least, Mr. Chen's daughters would believe that we respected and supported their efforts to help their father. I was also hopeful that the professional caregiving team would learn more about culturally competent care. When I spoke with the nurse manager for the unit, she understood my goals, discussed the situation with Mr. Chen's health care provider, and secured his approval for having the acupuncturist visit. I learned that the acupuncturist had to be credentialed by our hospital. While Mr. Chen's cancer did not respond to the acupuncture treatment, he did seem more comfortable, and his daughters couldn't thank me enough. I talked with them about how impressive their devotion to their father was and also mentioned that they may need to give him one last gift, the gift of "letting go." Unfortunately, I never saw this family again because this was my last week on this unit.

Melinda Ventura, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your competencies for professional practice? Can you think of other ways to respond?

What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve the quality and safety of care for patients like Mr. Chen?

Patient-Centered Care: How can you establish a successful partnership with family members discouraged by a patient's worsening condition who want to try CHAs? How did the nursing student promote respectful, person-centered, culturally competent care?

Teamwork and Collaboration/Quality Improvement: What factors do you think may have played a role in the health care provider's answer? Imagine if the nursing student (rather than the nurse manager) had approached the health care provider to allow the acupuncturist to visit. Do you think that the health care provider's answer would have been the same as it was when the manager conferred with him? Explain why or why not. What competencies do you need to develop to get the team to work well together? What needs to change to improve quality in this setting?

Safety/Evidence-Based Practice: What does the evidence point to as "best practice" in a situation like this? What safety needs does Mr. Chen have and how can you meet them?

Informatics: Can you identify the essential information that must be available in Mr. Chen's record to support safe patient care and coordination of care?

Can you think of other ways to respond to or approach the situation? What else might the nursing student have done to ensure a successful outcome?

Allopathic Medicine and Complementary Health Approaches

Allopathic medicine is a system in which medical doctors and other health care professionals, such as nurses,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

pharmacists, and therapists, treat symptoms and diseases using drugs, radiation, or surgery (NCI, n.d.a). Other terms for this type of approach are conventional medicine, biomedicine, mainstream medicine, orthodox medicine, and Western medicine (NCI, n.d.a). Allopathic medicine has been dominant for about 100 years in the United States and has spearheaded remarkable advances in biotechnology, surgical interventions, pharmaceutical approaches, and diagnostic tools. Allopathic medical care is particularly effective when aggressive treatment is needed in emergency or acute situations. However, allopathic medical care has not been totally effective in addressing the health of the whole person or in dealing with persistent symptoms related to chronic illness and patient quality of life (Helming et al., 2022). The CHA and allopathic systems differ fundamentally in several ways (Table 29-1). Until recently, the majority of decision making in CHAs has been based on observation, experience, and traditional healing manuscripts, in contrast to allopathic medicine, which has moved away from these methodologies to evidence-based practice. However, holistic nurses and other practitioners continue to advance the scientific knowledge base of evidence for holistic practice and for the effectiveness of holistic interventions (Helming et al., 2022).

Many CHAs are based on a theory and philosophy of holism upon which holistic nursing also is based. Many practitioners and consumers of health care choose to combine allopathic modalities and CHAs using an integrative approach. These concepts are discussed in the following sections.

Holism

Holism is a theory and philosophy that focuses on connections and interactions between parts of the whole; interrelationships of the physical, mental, emotional, sexual, cultural, social, spiritual, and energetic dimensions of the person (Helming et al., 2022). In contrast, the conventional scientific approach has focused on reductionism, reducing the human body to isolated parts rather than a unified whole, and in which treatment of health conditions focus on an individual organ or system rather than the whole being (Eliopoulos, 2018a). Using a holistic perspective, all living organisms, including humans, are continuously connecting and interacting with their environment. Further, parts of the organism, whether they are systems, subsystems, or cells, are also continuously interacting and changing. This continual interaction and change means that the body is not the sum of its parts (as in reductionism), but that it is a unified, dynamic whole.

Table 29-1 Beliefs Underlying Complementary and Alternative Therapies and the Allopathic Therapies

COMPLEMENTARY AND INTEGRATIVE HEALTH APPROACHES	ALLOPATHIC THERAPIES
Mind, body, and spirit are integrated and together influence health and illness.	Illness occurs in either the mind or the body, which are separate entities.
Health is a balance of body systems: mental, social, and spiritual, as well as physical.	Health is the absence of disease.
Illness is a manifestation of imbalance or disharmony.	The main causes of illness are considered to be pathogens (bacteria or viruses) or biochemical imbalances.
Symptoms are a sign or reflection of a deeper instability within the person; restoring physical and mental harmony will alleviate the symptoms. Healing is a slow process that involves the whole person.	Curing seeks to destroy the invading organism or repair the affected part.
Emphasis is on health. Healing is done by the patient; care is individualized.	Emphasis is on disease and high technology. Drugs, surgery, and radiation are among the key tools for dealing with medical problems.

Through the Eyes of a Nurse

Healing is a lifelong journey into understanding the wholeness of human existence. Along this journey, our lives mesh with those of patients, families, and colleagues, where moments of new meaning and insight emerge in the midst of crisis. Healing occurs when we help patients, families, and ourselves embrace what is feared most. It occurs when we seek harmony and balance. Healing is learning how to open what has been closed, so that we can expand our inner potentials. It is the fullest expression of oneself that is demonstrated by the light and shadow and the male and female principles that reside in each of us. It is accessing what we have forgotten about connections, unity, and interdependence. With a new awareness of these interrelationships, healing becomes possible, and the experience of the nurse as an instrument of healing and as a nurse healer becomes actualized. A nurse healer is one who facilitates

another person's growth toward wholeness (body–mind–spirit) or who assists another with recovery from illness or transition to peaceful death. Healing is not just curing symptoms. Rather, it is the exquisite blending of technology with caring, love, compassion, and creativity (p. xxiv).

—*Barbara Montgomery Dossey, Lynn Keegan*

Source: Dossey, B. M., & Keegan, L. (2016). *Holistic nursing: A handbook for practice* (7th ed.). Jones & Bartlett Learning. Used with permission.

Although someone might view holism as a recently developed belief system, holism in fact was the predominant belief throughout history until sometime before Descartes, a French philosopher who lived in the early part of the 17th century. Descartes and other influential thinkers asserted that the mind and body were separate from each other—mind–body dualism (Thibaut, 2018). That belief lasted until the early 20th century, when researchers began to prove that there was a connection between the mind and the body.

One of the 20th-century researchers, Selye (1976), developed the term *general adaptation syndrome* (GAS) to describe the general holistic pattern that emerges when people experience stress/illness. The GAS reflects a general response that occurs in various parts of the body. This theory holds that when someone is sick, that person is "sick all over," not just where symptoms manifest. Selye also demonstrated that adrenal exhaustion can be caused by emotional tension, such as suppressed rage or frustration. (For more on the GAS, see Chapter 43.)

A holistic philosophy underlies many CHA. People have a mind, body, emotions, and spirit that are connected and function as a unified whole. A change in any part of the organism will be reflected in other parts. When someone feels the emotion of sadness, that person may have a physical response of crying. In addition, when a person feels stressed and overwhelmed, the face and body language frequently reflect these conditions. However, there are also times when a person experiences physical symptoms, such as pain and fatigue, when there is no underlying pathophysiology in the body; rather, there may be psychosocial stressors which impact the body and a person's experience of daily life. Holism acknowledges that the body and mind interact as one; the healing of a person's symptoms in the body must also involve healing in the mind, and vice versa. "The goal is not to treat diseases but to serve the needs of the total person through the healing of the body, mind and spirit" (Eliopoulos, 2018b, p. 92).

Holistic nursing is nursing practice built on a holistic philosophy. Healing the whole person is its goal. Since holism is a philosophy and not a specific nursing role, holistic nurses can be found in all varieties of health care settings as well as in independent practice settings. In addition, holistic nurses frequently add CHAs to their practice. Most holistic nurses use CHAs for self-care, an essential component of holistic practice (AHNA, n.d.). The American Holistic Nurse Association (AHNA) promotes the education of nurses, other health care professionals, and the public in all aspects of holistic caring and healing (AHNA, n.d.).

Self-Care Alert

Nurses should practice self-care behaviors that promote wellness and resilience (American Association of Colleges of Nursing [AACN], 2021). Intentional use of holistic behaviors can be helpful in leading a healthful and less stressful life. What are you doing to support your well-being? Investigate various CHAs and consider how you might integrate CHAs into your plan for self-care.

Nurses are challenged to explore three questions in relation to uniting contemporary medical and surgical therapies with health rituals and complementary modalities (Helming et al., 2022, p. xxii):

. What do we know about the meaning of healing?
. What can we do each day to facilitate healing?
. How can we be an instrument in the healing process?

Read through the accompanying Through the Eyes of a Nurse and reflect on your commitment to holistic, person-centered nursing and healing. Holistic nursing is recognized as a nursing specialty by the American Nurses Association (AHNA, n.d.). The AHNA also provides published standards for holistic nursing practice (AHNA & ANA, 2019). Registered nurses can become certified in basic and advanced holistic nursing through the American Holistic Nurses Credentialing Corporation (AHNCC, 2020).

Integrative Care

A person who uses integrative care uses some combination of allopathic medicine and CHAs (Table 29-2). There are several types of integrative care models used throughout the United States that can be housed in virtually all health care delivery structures. Optimally, these models include sensitive and knowledgeable health care providers who work with patients to design a plan of care that is responsive to the patient's and family's/caregiver's preferences and needs and combines the best of allopathic medicine and CHAs while avoiding harmful interactions (Helming et al., 2022).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Table 29-2 Integrative Care of the Common Cold[a]

COMPLEMENTARY AND INTEGRATIVE HEALTH APPROACHES	ALLOPATHIC APPROACHES
Acupuncture to appropriate areas to reduce sinus congestion	Decongestant over-the-counter medications
Rest and fluids	Rest and fluids

[a]In this example, adding herbs and/or acupuncture to a typical allopathic approach would represent integrative care.

Complementary Health Approaches and Nursing

CHAs consist of a large variety of therapies that are based on a set of beliefs different from those of allopathic medicine. Some of these modalities have developed fairly recently (e.g., guided imagery), while others have been used for thousands of years as components of ancient healing systems (e.g., Ayurveda or traditional Chinese medicine). Some therapies can be used effectively without assistance (e.g., nutritional approaches, deep breathing exercises), while others (e.g., naturopathy, acupuncture) are more effective when used with guidance from practitioners who have particular knowledge and expertise.

Many people use CHAs for stress management/reduction (NCCIH, 2020b). Techniques such as relaxation with focused breathing, meditation, imagery, biofeedback, and massage are used in all stages of health and illness to promote healing and/or manage symptoms. Because stress can contribute to illness, CHAs can sometimes be effective in reducing symptoms and enhancing quality of life. Nurses can assist patients—and themselves—with these therapies. Refer to the Research in Nursing display regarding the use of yoga and mindfulness in relation to stress in children and adolescents with asthma.

Recall **Sylvia Puentes**, the anxious patient scheduled for surgery. The nurse's knowledge of CHAs would be important in helping this patient to reduce her preoperative anxiety. The nurse could discuss various methods available, allowing the patient to select the one that seems best for her. Such actions help develop a trusting nurse–patient relationship and foster a sense of self-esteem in the patient by allowing her to participate in the plan of care and decision making.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Yoga and Mindfulness

Stress is considered a significant trigger for physical and mental health issues, including asthma in children (Lack et al., 2020). Children with asthma experience impaired quality of life, symptoms of anxiety and impaired ability to participate in physical activity (Lack et al., 2020). Many therapies maybe helpful in reducing stress, resulting in enhanced health management and improved quality of life for these patients.

Related Research

Lack, S., Brown, R., & Kinser, P. A. (2020). An integrative review of yoga and mindfulness-based approaches for children and adolescents with asthma. *Journal of Pediatric Nursing, 52*, 76–81. https://doi.org/10.1016/j.pedn.2020.03.006

The purpose of this integrative review was to examine the use of yoga and mindfulness for children and adolescents with asthma. A comprehensive search of five databases was completed to identify studies addressing the physiologic and psychological health effects of yoga and mindfulness in children and adolescents (aged 19 years and younger) with asthma. Data bases searched included PubMed/MEDLINE, PsychINFO, Web of Science, EMBASE, and CINAHL, from the launch of the database through January 2020. Keywords included "yoga," mindfulness," and

"asthma." The authors also searched the reference lists of articles (ancestry approach) to identify publications in addition to those identified as a result of the database searches. An initial review of titles and abstracts was followed by full-text review. Studies were included if the participants were ages 19 years and younger and if the study examined yoga and asthma, mindfulness and asthma, and yoga and mindfulness and asthma. Studies were excluded if the participants were adults or mixed data of children and adults; and if the articles were review articles, commentaries, editorials, abstracts, and poster sessions. A total of 11 articles met the criteria for review from the years 1991 to 2019.

A variety of study designs were used in the reviewed articles, including pilot, single-subject, and correlational studies. Four studies used a control group, and one was longitudinal. The studies were carried out in eight countries. Two of the studies assessed mindfulness in adolescents with asthma; nine studies evaluated yoga as intervention for children and adolescents with asthma. The majority of studies of a yoga-based intervention identified that the use of yoga by children and adolescents is associated with improved lung function, anxiety, and quality of life. The studies of a mindfulness intervention suggested that higher rates of trait mindfulness were associated with lower rates of wheezing and coughing and were related to decreased asthma-specific stress and improved asthma control and quality of life. The authors concluded that there are preliminary indications to support the use of yoga and mindfulness for enhancing the physical and psychological health of children and adolescents with asthma.

Relevance to Nursing Practice

The use of CHAs, such as yoga and mindfulness, offer the potential help decrease stress and anxiety resulting in positive effects on the physical and psychological health of patients. Nurses have an important role in helping patients to manage self-care and health problems and issues. Yoga and mindfulness are inexpensive and easy to implement approaches that offer the potential for symptom management and self-regulation of asthma triggers and other effects of stress and anxiety.

Use of Complementary Health Approaches in the United States

The most comprehensive and reliable findings to date on Americans' use of CHAs are released by the National Center for Complementary and Integrative Health (NCCIH), part of the National Institutes of Health, and the National Center for Health Statistics (NCHS), part of the Centers for Disease Control and Prevention (CDC). The following findings are based on the 2017 edition of the NCHS National Health Interview Survey (NHIS), a study in which tens of thousands of Americans are interviewed about their health- and illness-related experiences. The report is available, along with a press release and graphics, at https://www.nccih.nih.gov/research/statistics/nhis/2017.

Prevalence of Complementary Health Approaches

The annual NHIS by the NCCIH includes a special section on CHAs every 5 years. The 2012 NHIS found that, in the United States, approximately 30% of adults (about 3 in 10) and approximately 12% of children (about 1 in 9) were using some form of CHAs in the 12 months before the survey (Clarke et al., 2015). In 2012, CHA use was more prevalent among women, adults ages 30 to 69 years, adults with higher levels of education, adults who were not poor, adults living in the West, former smokers, and adults who were hospitalized in the last year. Adults younger than age 65 years and those with private health insurance were more likely than those with public health insurance or uninsured adults to use CHAs. There also are cultural variations. In 2012, the use of CHAs in non-Hispanic Whites was 37.9%, in Hispanics was 22%, and non-Hispanic Blacks was 19.3% (Clarke et al., 2015). There was a decrease in use of CHAs by poor adults (those who have an annual income at the national poverty threshold) from 26.6% in 2007 to 20.6% in 2012 (Clarke et al., 2015).

Past NHIS research identified yoga, meditation, and seeing a chiropractor as some of the most commonly used CHAs (Clarke et al., 2015). The 2017 NHIS examined changes over time in the percentage of adults who used yoga, meditation, and chiropractors in the 12 months before the survey as well as variation by biologic sex, age, and race and Hispanic origin (Clarke et al., 2018). This survey data identified increases from 2012 to 2017 in the use of yoga, meditation, and chiropractors (Clarke et al., 2018). Yoga was the most commonly used CHA among adults ages 18 years and older, increasing from 9.5% (2012) to 14.3% (2017) (Clarke et al., 2018). Participants who identified as women were more likely to use yoga, meditation, and chiropractors during the survey period than participants who identified as men (Clarke et al., 2018). Non-Hispanic White adults were more likely to use yoga, meditation, and chiropractors compared with Hispanic and non-Hispanic Black adults (Clarke et al., 2018). Other commonly used CHAs are nonvitamin, nonmineral, and natural products (17.7%); deep breathing exercises (10.9%); yoga (9.5%); chiropractic or osteopathic manipulation (8.4%); meditation (8%); and massage (6.9%) (Clarke et al., 2015). Of all the natural products, fish oil and glucosamine, chondroitin, or a combination supplement were the products most commonly used by adults in 2012 (Clarke et al., 2015).

The NHIS is an annual survey conducted by the NCHS about health and health care use (Clarke et al., 2015; Jou & Johnson, 2016). One component of this survey is a CHA supplement, asking adults in the United States older than age 18 years about communication and disclosure with their primary care physician in relation to the use of CHAs. One third

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

of the 7,493 participants indicated they use CHAs; however, 42.3% of these CHA users indicated that they do not discuss CHA use with their primary care physician (Clarke et al., 2015; Jou & Johnson, 2016). Participants reported most nondisclosure was related to physicians not asking about CHA use or to concerns about physician knowledge regarding CHAs (Clarke et al., 2015; Jou & Johnson, 2016). These findings highlight the need for nurses to ask about CHA use at every patient visit and to emphasize that it is important to discuss CHA use with their health care providers. Patients should be proactive and initiate conversation about their use of CHAs, providing information about any CHAs they are using or considering for use (NCCIH, 2020e).

Reasons for Using Complementary Health Approaches

People use CHAs for an array of conditions and reasons. In general, people who choose CHAs are seeking ways to improve their health and well-being or to relieve symptoms associated with chronic, even terminal, illnesses or the side effects of conventional treatments for them. Other reasons for choosing to use CHAs include having a holistic health philosophy or a transformational experience that changes one's worldview and wanting greater control over one's own health. For example, people may use CHAs for pain conditions such as back, neck, or joint pain. The type of CHA implemented appears to be related to the most common outcomes of their use. For example, studies suggest possible benefits of yoga for several aspects of wellness, with practitioners of yoga commonly reporting positive stress management; mental and emotional health; healthy activity habits; promotion of sleep; and positive effects on relief of back and neck pain (NCCIH, 2019a).

Use of Complementary Health Approaches With Children

In 2012, the CHAs most commonly used by U.S. children in the 12 months prior to the survey included nonvitamin, nonmineral, and natural products (4.9%); chiropractic or osteopathic manipulation (3.3%); yoga (3.1%); deep breathing (2.7%); and homeopathic treatment (1.8%) (Black et al., 2015). Back or neck pain, head or chest cold, other musculoskeletal conditions, anxiety or stress, and attention-deficit hyperactivity disorder were the most common reasons for use of a CHA reported in children (Black et al., 2015).

Similar to the NHIS survey results indicating an increase in use of yoga and meditation in adults older than age 18 years, data from the 2017 NHIS found that the use of yoga and meditation significantly increased among U. S. children ages 4 to 17 years (Black et al., 2018). The percentage of children using yoga in the 12 months prior to the survey increased from 3.1% (2012) to 8.4% (2017) (Black et al., 2018). The use of meditation increased from 0.6% (2012) to 5.4% (2017) (Black et al., 2018).

Box 29-1 Complementary Health Approaches: Be an Informed Consumer

- Take charge of your health by being an informed consumer.
- Talk with your health care providers when making any decisions about using complementary health approaches. Your health care providers can give you advice based on your medical needs.
- If you are thinking about using a CHA therapy, learn the facts. Is it safe? Does it work?
- Find out what scientific studies have been done. It is not a good idea to use a CHA therapy simply because you have seen it in an advertisement or on a website or because people have told you that it worked for them.
- Keep in mind that the number of websites offering health-related resources grows every day. Many sites provide valuable information, while others may have information that is unreliable or misleading. To evaluate the quality of a website, take a look at who runs the site, who pays for it, and the purpose of the site. Also, check out where the information comes from, how it is selected, and how current it is.
- Scientific research on many CHA therapies is relatively new, so information about safety and effectiveness may not be available for every therapy. However, many studies of CHA treatments are underway, and researchers are always learning more about CHA.
- You can find reliable information on CHA through the National Institutes of Health's National Center for Complementary and Integrative Health (NCCIH). The NCCIH website (http://nccih.nih.gov) provides a variety of useful information as well as links to other trustworthy sources.

Source: Adapted from NCCIH. (2015). Be an informed consumer. https://nccih.nih.gov/health/decisions; National Center for Complementary and Integrative Health (NCCIH). (2020, February). *Be an informed consumer*. https://www.nccih.nih.gov/health/be-an-informed-consumer

Growth of the Complementary Health Approaches Industry

In 2012, 59 million Americans spent $30.2 billion out-of-pocket on CHAs (NCCIH, 2016e). The AACN identifies the need for nursing students to develop an understanding of holistic person-centered care that has healing the whole person as its goal (AACN, 2021). Approximately one half of medical schools in the United States offer at least one CAM course or clinical practice rotation (Cowen & Cyr, 2015). Insurers increasingly pay for selected CHAs for particular identified conditions (American Cancer Society, 2015). Scores of private organizations provide classes and workshops

for consumers as well as education and practical experience for health care providers.

Many private and governmental organizations have been developed to address CHAs. The NCCIH funds research on CHAs and is a great first resource for professionals and the public seeking information about CHAs. Health care professionals and consumers can find valuable information about the safety and efficacy of CHAs on the NCCIH website at https://www.nccih.nih.gov/. Refer to Box 29-1 for additional advice to the public about being an informed consumer.

The U.S. Food and Drug Administration (FDA) regulates dietary supplements and provides guidance for consumers seeking health-related information about dietary supplements. The FDA (n.d.) offers consumers "5 Things to Consider Before Taking a Dietary Supplement," a guide to making informed decisions about using supplements (Fig. 29-1 on page 890). The guideline includes a warning that if "claims sound too good to be true, they probably are" and a reminder that the term "natural" does not always mean "safe" (U.S. FDA, n.d.). Even with these tips, fraudulent health products are not always easy to spot. The FDA recommends that people check with a physician or other health care provider when tempted to purchase or use an unproven product or one with questionable claims. Consumers can subscribe to the FDA Podcasts and News Feeds to access up-to-date information on fraudulent and/or tainted products as well as other drug, food, and health topics to help keep from being duped or hurt by these products (U.S. FDA, 2020).

Box 29-2 Complementary Health Approach Categories

Mind–body practices use a variety of techniques designed to enhance the mind's ability to affect bodily function and symptoms. Examples include yoga, chiropractic and osteopathic manipulation, meditation, acupuncture, relaxation techniques (e.g., breathing exercises, guided imagery), tai chi, Pilates, energy medicine, and others.

Natural products include the use of botanicals (herbs), vitamins, minerals, fatty acids, amino acids, proteins, prebiotics and probiotics, whole diets, and functional foods.

Other CHAs do not fit into either of the two previous groups and include traditional healers, Ayurveda medicine, homeopathy, traditional Chinese medicine, naturopathy, and functional medicine.

Source: National Center for Complementary and Integrative Health (NCCIH). (2020a). https://www.nccih.nih.gov/health/complementary-alternative-or-integrative-health-whats-in-a-name

COMPLEMENTARY HEALTH APPROACHES CATEGORIES

NCCIH (2020a) classifies the major CHAs into three categories: mind–body practices, natural products, and other CHAs. Each category contains several therapies. For example, meditation is a therapy included in the mind–body category. Box 29-2 describes each of these categories. Table 29-3 (on pages 891–892) lists examples of therapies from these categories that are used to address pain, describing what they help and how they work. Information on some of the most widely used CHAs of interest to nurses is discussed in the following sections.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

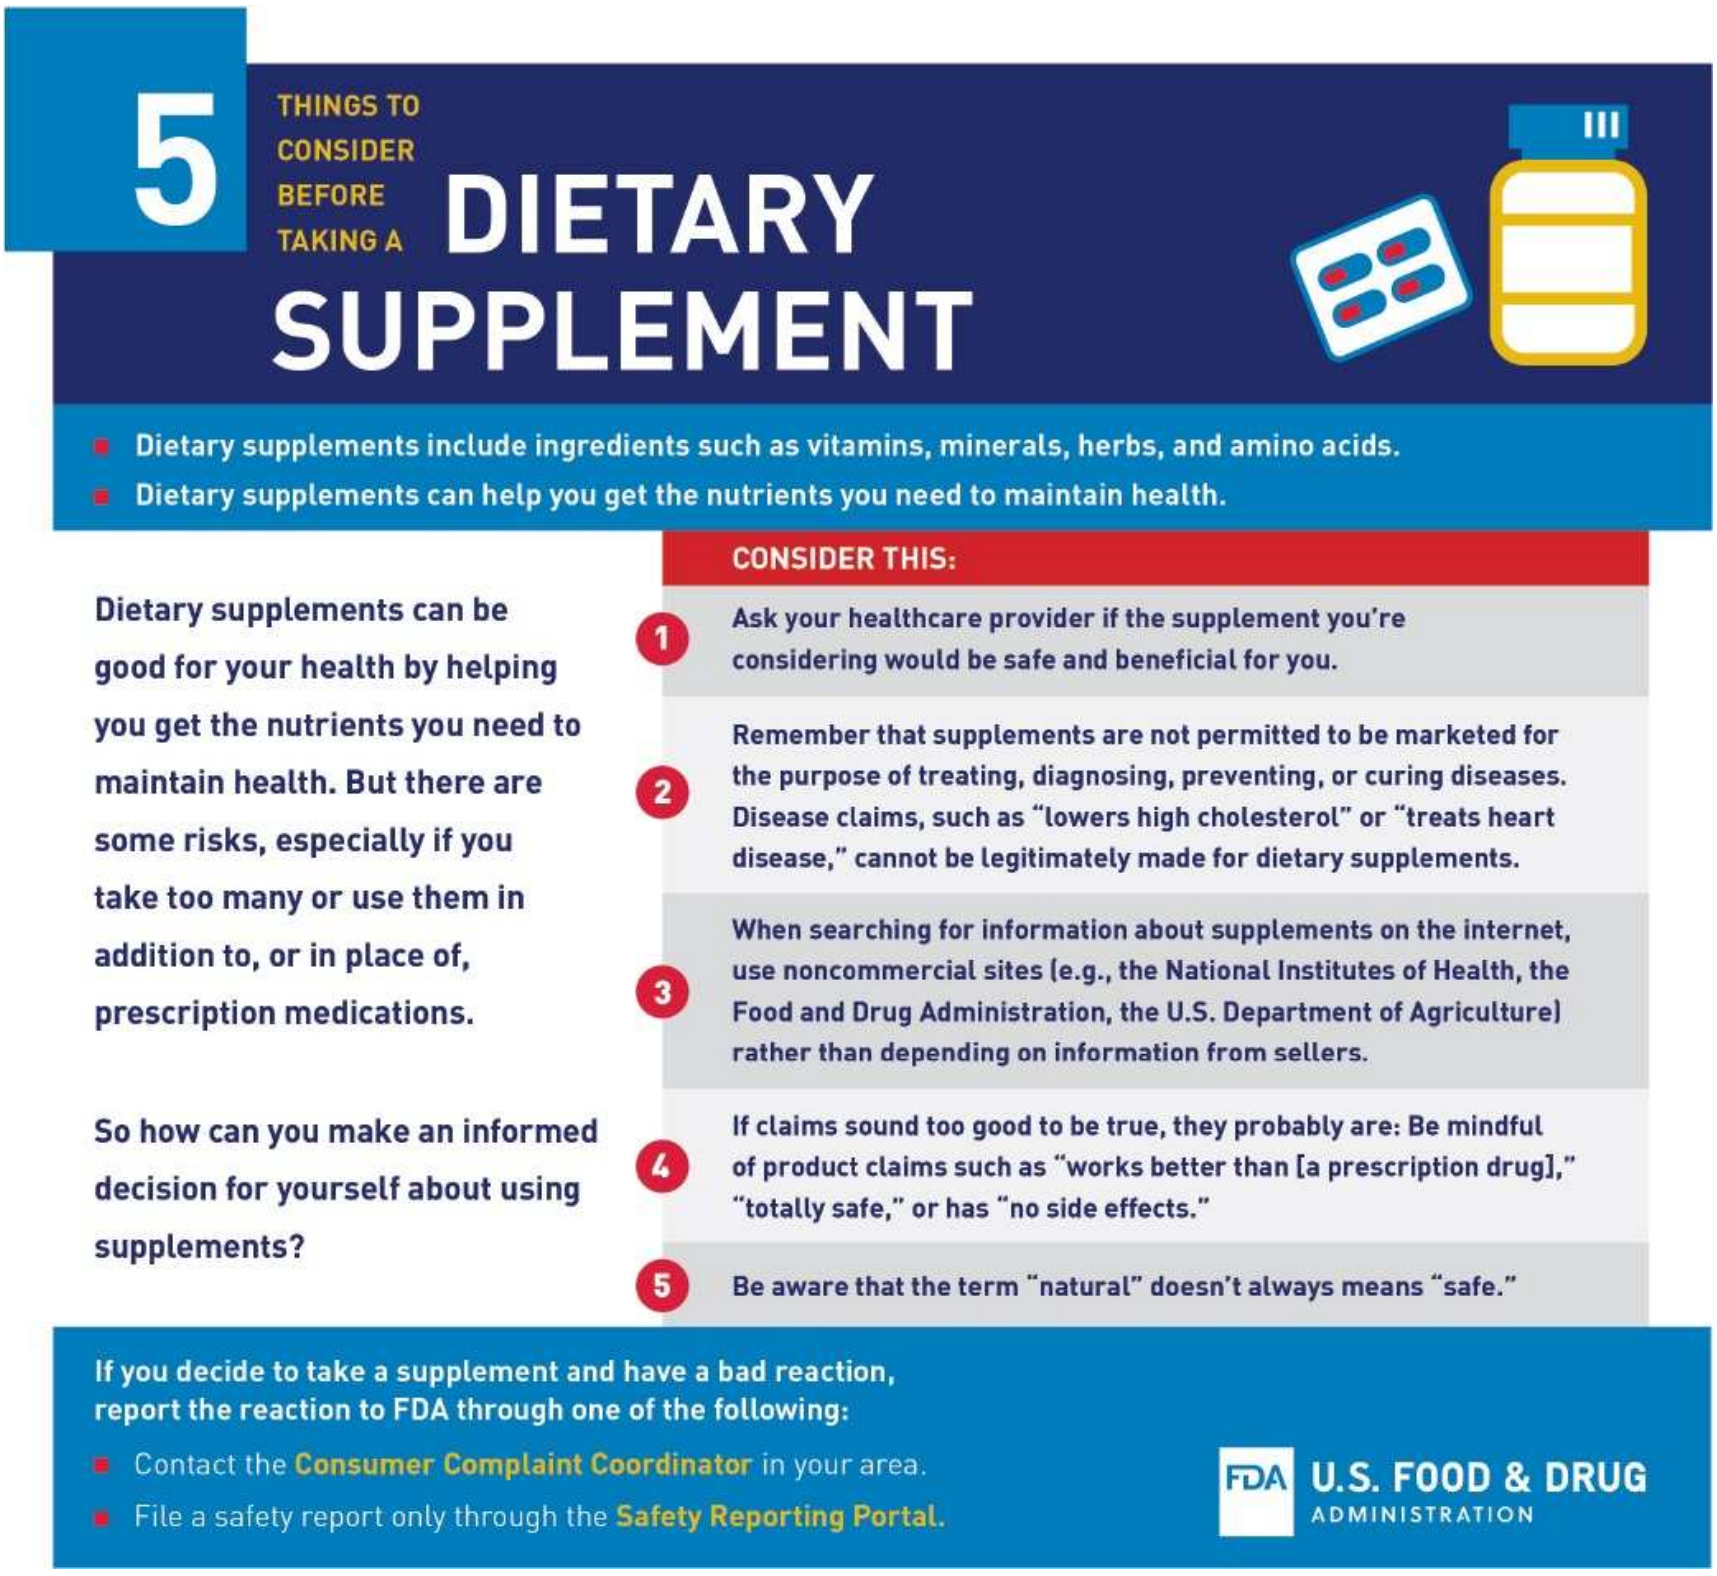

FIGURE 29-1. A guide to making informed decisions about the use of supplements. (*Source:* U.S. Food and Drug Administration (FDA). [n.d.]. *5 things to consider before taking a dietary supplement*. https://www.fda.gov/media/106435/download)

Mind–Body Practices

Many people recognize that there is a strong mind–body connection. Common everyday occurrences indicate that some connection does indeed exist. For example, students may experience insomnia related to anxiety the night before a major examination or suffer a migraine headache triggered by a fight with a spouse or good friend. Recent research has expanded our knowledge of how the mind and body communicate with each other. The scientific field of psychoneuroimmunology (PNI) addresses the effect of the mind on health and resistance to disease, investigating the connections among psychology, neuroendocrinology, and immunology (Helming et al., 2022). Chemicals such as cortisol have been found to be associated with stress and immunosuppression during anaphylaxis allergic reaction (Moraes et al., 2018). Neuropeptides are another chemical found to have properties that allow them to affect neurologic and physiologic tissue receptors. Many neuropeptide receptor sites lie along the gastrointestinal (GI) tract; this explains why people can experience a large variety of GI symptoms in response to emotional situations.

Knowing how this communication between the mind and body occurs assists in the understanding of the mind–body modalities, which may be useful for patients and others as well as self-care for nurses. Psychoneuroimmunology-based interventions can be used to control symptoms and improve a patient's quality of life (Moraes et al., 2018). Intentional use of mind–body interventions to invoke the relaxation response has been suggested to help patients control stress, manage pain, fatigue, and anxiety, and improve sleep quality (Georga et al., 2019; Kiley et al., 2018; Labus et al., 2019).

Table 29-3 Complementary and Integrative Health Approaches That Work on Pain

TYPE	WHAT THEY HELP	HOW THEY HELP	EXAMPLES
Mind–body practices that are movement-based:	Musculoskeletal pain, joint pain, and lower-back pain	By strengthening muscles, supporting joints, improving	• *Physical therapy:*

Physical exercises and practices		alignment, and releasing endorphins	Specialized movements to strengthen weak areas of the body, often through resistance training • *Yoga:* An Indian practice of meditative stretching and posing • *Pilates:* A resistance regimen that strengthens core muscles • *Tai chi:* A slow, flowing Chinese practice that improves balance • *Feldenkrais:* A therapy that builds efficiency of movement
Natural products—nutritional and herbal remedies: Food choices and dietary supplements (ask your doctor before using supplements)	All chronic pain but especially abdominal discomfort, headaches, and inflammatory conditions, such as rheumatoid arthritis	By boosting the body's natural immunity, reducing pain-causing inflammation, soothing pain, and decreasing insomnia	• *Anti-inflammatory diet:* A Mediterranean eating pattern high in whole grains, fresh fruits, leafy vegetables, fish, and olive oil • *Omega-3 fatty acids:* Nutrients abundant in fish oil and flaxseed that reduce inflammation in the body • *Ginger:* A root that inhibits pain-causing molecules • *Turmeric:* A spice that reduces inflammation • *MSM:* Methylsulfonylmethane, a naturally occurring nutrient that helps build bone and cartilage
Other mind–body approaches: Using the powers of the mind to produce changes in the body	All types of chronic pain	By reducing stressful (and, hence, pain-inducing) emotions such as panic and fear and by refocusing attention on subjects other than pain	• *Meditation:* Focusing the mind on something specific (such as breathing or repeating a word or phrase) to quiet it • *Guided imagery:* Visualizing a particular outcome or scenario with the goal of mentally changing one's physical reality • *Biofeedback:* With a special machine, becoming alert to body processes, such as

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

			muscle tightening, to learn to control them • *Relaxation:* Releasing tension in the body through exercises such as controlled breathing
Energy healing: Manipulating the electrical energy—called *chi* in Chinese medicine—emitted by the body's nervous system	Pain that lingers after an injury heals, as well as pain complicated by trauma, anxiety, or depression	By relaxing the body and the mind, distracting the nervous system, producing natural painkillers, activating natural pleasure centers, and manipulating chi	• *Acupuncture:* The insertion of hair-thin needles into points along the body's meridians, or energetic pathways, to stimulate the flow of energy throughout the body; proven helpful for postsurgical pain and dental pain, among other types • *Acupressure:* Finger pressure applied to points along the meridians, to balance and increase the flow of energy • *Qi gong:* Very slow, gentle physical movements, similar to tai chi, that cleanse the body and circulate chi • *Reiki:* Moving a practitioner's hands over the energy fields of the patient's body to increase energy flow and restore balance
Physical manipulation: Hands-on massage or movement of painful areas	Musculoskeletal pain, especially lower back and neck pain; pain from muscle underuse or overuse; and pain from adhesions or scars	By restoring mobility, improving circulation, decreasing blood pressure, and relieving stress	• *Massage:* The manipulation of tissue to relax clumps of knotted muscle fiber, increase circulation, and release patterns of chronic tension • *Chiropractic:* Physically moving vertebrae or other joints into proper alignment, to relieve stress • *Osteopathy:* Realigning vertebrae, ribs, and other joints, as with chiropractic; osteopaths have training equivalent to that of medical doctors
Lifestyle changes: Developing healthy habits	All types of chronic pain	By strengthening the immune system and	• *Sleep hygiene:*

at home and work	enhancing well-being and by reframing one's relationship to (and, thus, experience of) chronic pain	Creating an optimal sleep environment to get deep, restorative rest; strategies include establishing a regular sleep–wake schedule and minimizing light and noise • *Positive work environment:* Having a comfortable workspace and control over one's activities to reduce stress and contribute to the sense of mastery over pain • *Healthy relationships:* Nurturing honest and supportive friendships and family ties to ease anxiety that exacerbates pain • *Exercise:* Regular activity to build strength and lower stress

Source: Research suggests these therapies can ease discomfort. For more information, visit the website of the National Center for Complementary and Integrative Health (www.nccih.nih.gov).

Think back to **Sylvia Puentes**, the anxious preoperative patient. The nurse would need to incorporate an understanding of the mind–body connection when discussing possible suggestions for anxiety relief.

Relaxation

Relaxation techniques promote parasympathetic nervous system activity, helping to reduce sympathetic activity and restore the balance of the two systems. The complex psychophysiologic processes that activate to deal with a real or perceived emergency, characterized by increased sympathetic nervous system activity, can contribute to symptoms such as increased blood pressure, cool hands and feet, tight muscles, increased heart rate, and increased anxiety. The ultimate goal is to increase the parasympathetic system influence in the mind–body and thus reduce the effect of stress and stress-related illness on the body.

Relaxation can be useful whether a patient is experiencing a single stressful event, such as surgery or chronic stress. Patient benefits include reduced anxiety, reduced muscle tension and pain, improved functioning of the immune system, enhanced sleep and rest, and an improved overall sense of well-being (NCCIH, 2021). Relaxation techniques include progressive muscle relaxation, guided imagery, deep breathing exercises, autogenic training, biofeedback, and self-hypnosis (NCCIH, 2021). Because these modalities are quite different, the type of relaxation modality chosen needs to be individually suited to the patient, based on their health status, personal preferences, and available time.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Recall **Mr. Chen**, the 65-year-old man dying of lung cancer. The nurse needs to include the patient's daughters when developing the plan of care. Therefore, when interacting with the patient's daughters, the nurse would also assess their stress level as they cope with their father's deteriorating condition. This assessment could provide valuable information about the cultural beliefs and values of each daughter, leading the nurse to suggest possible culturally appropriate methods for relaxation.

Nurses can assist patients and others to begin to achieve a relaxation response by focusing on their breathing. Patients can lengthen their breathing or focus on abdominal or diaphragmatic breathing. Benson (1975) found it helpful to use a mental device such as a repetitive phrase to remind the body to relax. Nurses can also practice relaxation as part of their self-care, enabling them to better deal with personal and work-related stress. Relaxation exercises can be done anywhere, at any time, and without cost.

Meditation

Meditation has been part of many spiritual and healing traditions for hundreds of years. Meditation refers to a group of techniques, such as mantra meditation, relaxation response, mindfulness meditation, and Zen Buddhist meditation. In meditation, a person learns to focus attention. Some forms of meditation instruct the practitioner to become mindful of thoughts, feelings, and sensations and to observe them in a nonjudgmental way. This practice is believed to result in a state of greater calmness and physical relaxation, as well as psychological balance (NCCIH, 2021). Practicing meditation can change how a person relates to the flow of emotions and thoughts.

Most types of meditation have four elements in common (NCCIH, 2016b):

- *A quiet location:* Meditation is usually practiced in a quiet place with as few distractions as possible. This can be particularly helpful for beginners.
- *A specific, comfortable posture:* Depending on the type being practiced, meditation can be done while sitting, lying down, standing, walking, or in other positions.
- *A focus of attention:* Focusing one's attention is usually a part of meditation. For example, the meditator may focus on a mantra (a specially chosen word or set of words), an object, or the sensations of the breath. Some forms of meditation involve paying attention to whatever is the dominant content of consciousness.
- *An open attitude:* Having an open attitude during meditation means letting distractions come and go naturally without judging them.

Patients seeking inpatient care might have a meditation practice they want to continue. Nurses should provide the time necessary for this to occur. Nurses could benefit from a meditation practice as well and could practice a brief meditation during breaks from patient care activities.

Guided Imagery

Guided imagery focuses on evoking pleasant images to replace negative or stressful feelings and to promote relaxation. Guided imagery involves using all five senses to imagine an event or body process unfolding according to a plan. When all senses are involved in the experience, the imaginary situation is more fully encoded in the body and more likely to take place. A relaxation technique is frequently used to prepare the mind and body before beginning an imagery session. Nurses can assist patients and others with imagery in several ways (Quinn, 2019):

- Many kinds of recorded imagery material with scripts are available so that people can use them independently. If some of these are available on the nursing unit, patients can determine what types of recorded material they would like to use or purchase. Patients can also be assisted to write a script and record it for their own use.
- Nurses can work with patients using a picture or photograph to visualize the desired outcome in a body part or in a situation. Patients can add to the visual cue and develop a total image.
- During a painful or stressful event, such as an intravenous line being started, the patient can "go to a favorite place" and imagine being there with all the pleasant experiences related to that space.

Think back to **Sylvia Puentes**, the anxious patient scheduled for surgery. Any of these types of imagery techniques would be appropriate suggestions for the patient. However, the nurse needs to assess the patient's preferences, beliefs, and ability to participate in these techniques to determine the best recommendation.

Yoga

Yoga is a mind and body practice with historical origins in ancient Indian philosophy. In the United States, yoga is practiced independently or paired with other health-promoting activities that assist people to achieve unity and wholeness. In general, in the United States, yoga involves the combination of physical movements, breathing practices, and relaxation practices/meditation (NCCIH, 2019a). Yoga promotes strength and flexibility, increases endurance and relaxation, reduces a person's response to stress, promotes healthy eating/activity habits, and promotes sleep (NCCIH, 2019a; Sivaramakrishnan et al., 2019). Yoga has been incorporated into comprehensive integrative pain management interventions (Pearson et al., 2020) and supportive interventions to address the negative side effects of cancer treatment (Johnson & Haag, 2019). Breathing exercises, posture awareness, spiritual practices, and mind–body centering can be added to the basic postures. Basic yoga postures are illustrated in Figure 29-2 on page 894. Common styles or traditions of yoga include (Yoga Alliance, n.d.):

- Iyengar, which focuses on proper alignment of the body and use of poses and breathing to address specific needs of the practitioner
- Kripalu or "gentle yoga," which focuses on relaxation and coming into balance
- Ashtanga, which focuses on synchronizing breathing with a fast-paced series of postures
- Bikram, which is done in a studio heated to 105°F and involves 26 set postures

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 29-2. Sample yoga poses.

Yoga can be used throughout the lifespan (Fig. 29-3); for example, yoga has been associated with improvement in physical function and health-related quality of life outcomes in older adults (Sivaramakrishnan et al., 2019). Some postures are contraindicated after surgery and in the presence of disease. Consumers can stream yoga classes or attend yoga classes in-person. Encourage patients to find a type of yoga that is compatible with their physical condition and goals.

Qi Gong and Tai Chi

Qi gong is a system of postures, exercises (both gentle and dynamic), breathing techniques, and visualization. The majority of qi gong exercises or meditations enhance systemic health. They are designed to restore the healing system, the body's innate intelligence, so it knows how to correct and heal itself. Qi gong postures are illustrated in Figure 29-4. For techniques specific to particular diseases, a patient can consult a qi gong teacher.

Tai chi, a martial arts, mind–body practice (Fig. 29-5) that likely developed from qi gong, has been shown to be better than brisk walking in reducing several cardiovascular disease risk factors and improving psychosocial well-being (Chan et al., 2018). Both tai chi and qi gong (also known as qigong) have origins in China and involve physical movement, mental focus, deep breathing, and relaxation (NCCIH, 2016b). As with yoga, qi gong and tai chi can be learned through the use of streamed or face-to-face classes. Various tai chi and qi gong organizations offer training and certification programs, with differing criteria and levels of certification for instructors (NCCIH, 2016b). Encourage those interested to ask potential instructors about their background and knowledge.

FIGURE 29-3. A woman practicing yoga.

Acupuncture

Acupuncture addresses a person's qi. Traditionally, Qi (*chi* in Japanese) is believed to flow vertically in the body through an intricate structure of 12 primary meridians, energy circuits that nourish and support all cells and organs of the body (Fig. 29-6). Acupuncture consists of placing very thin, short, sterile needles at particular acupoints, believed to be centers of nerve and vascular tissue, along a meridian (Figs. 29-7 on page 896 and 29-8 on page 896). Acupuncture either increases or decreases the flow of qi along the meridian, restoring the balance of yin and yang. This change in the flow of energy contributes to healing. Conventional medicine suggests acupuncture stimulates improved biochemical actions involved in nerve transmission, direct effects on the central nervous and modulation of parasympathetic activity (Koppelman, n.d.).

FIGURE 29-4. Qi gong postures.

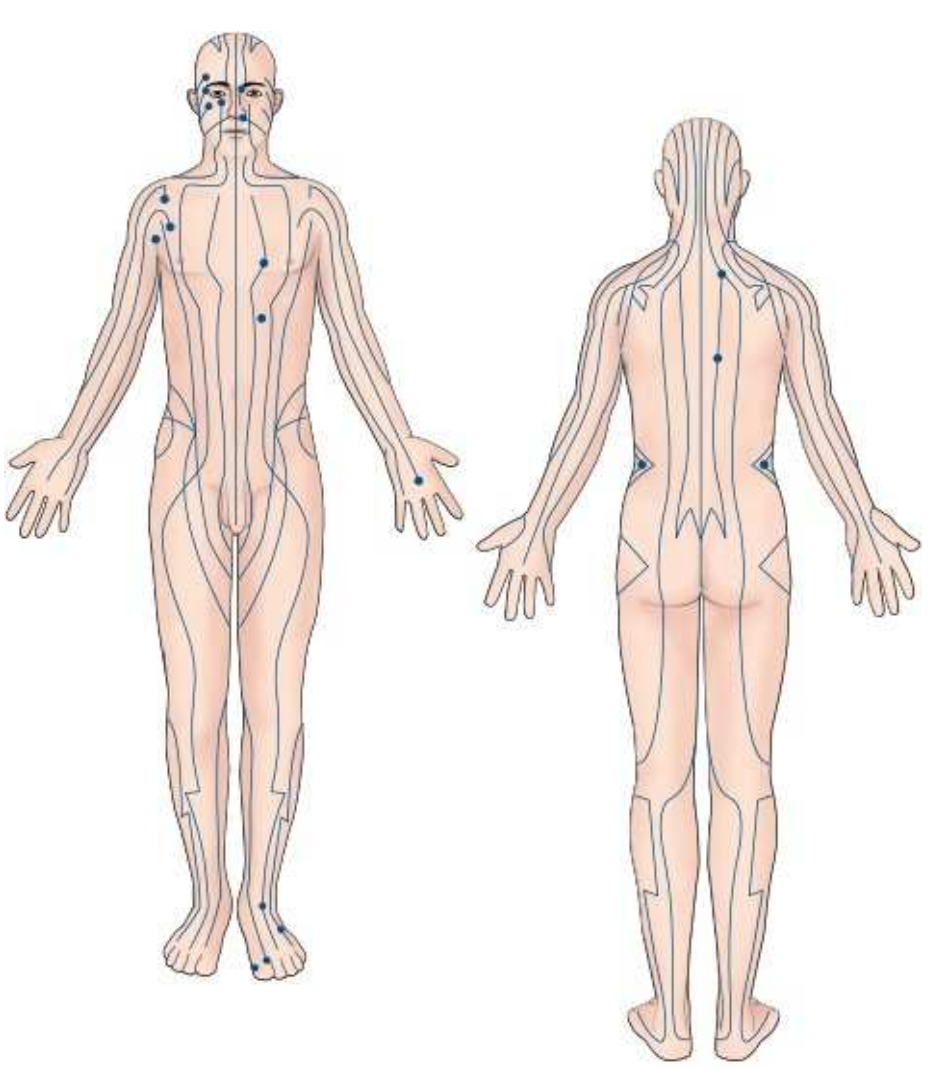

FIGURE 29-6. Acupuncture meridians.

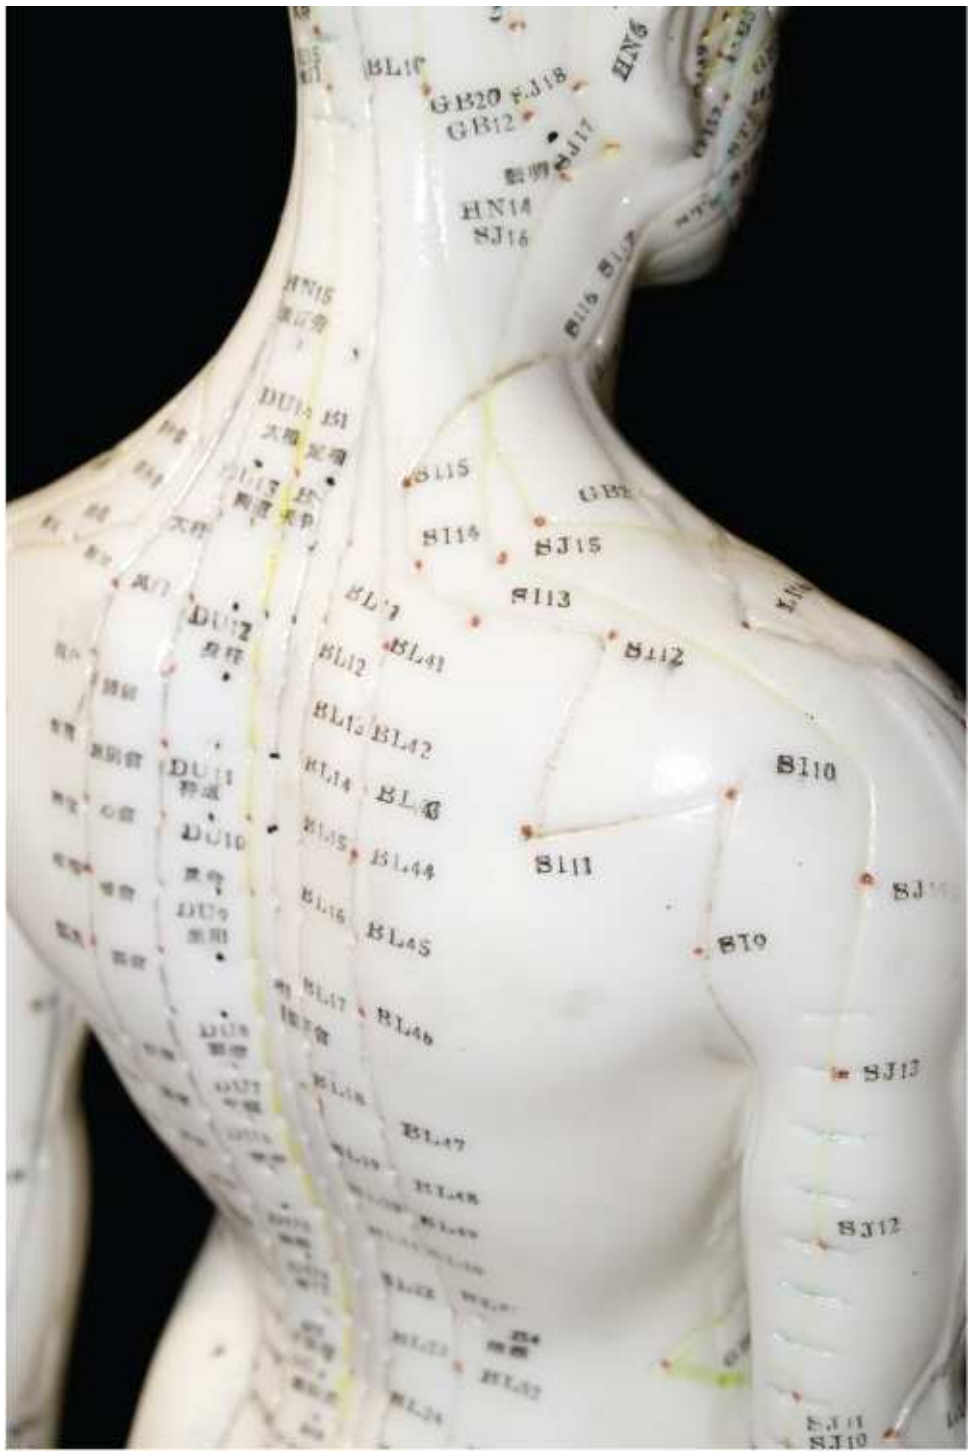

FIGURE 29-7. Model of acupuncture points on the body. (*Source: Photo by Cora Reed/Shutterstock.*)

Think back to **Lee Chen**, the terminally ill patient whose daughters asked for an acupuncturist. When developing the plan of care, the nurse would need to investigate Mr. Chen's culture and examine the beliefs associated with acupuncture. Based on an understanding of this information, the nurse would be better prepared to advocate for the patient and his daughters.

Acupuncture is used for a variety of reasons, including reducing pain, promoting adherence to smoking cessation, addressing sleep disorders, and minimizing nausea and vomiting due to chemotherapy and pregnancy (AAMA, n.d.). Licensed acupuncturists have graduated from an accredited acupuncture school after significant college-level coursework. In addition, they have passed a licensure examination. However, education and training standards and requirements vary from state to state (NCCIH, 2016c). Acupuncture is generally provided in clinics or private offices, although it is possible for acupuncturists to provide acupuncture on inpatients. A growing number of physicians are offering acupuncture as part of integrative health care practice; when acupuncture is administered by physicians, it's called medical acupuncture. These physicians are trained in both conventional medicine and acupuncture (AAMA, n.d.).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 29-8. An acupuncture needle applied to a woman's scalp. (*Source: Photo by Cultura Motion/Shutterstock*.)

Consider **Mr. Chen**, the terminally ill patient whose daughters requested that he receive acupuncture. Applying the theory underlying acupuncture's believed mechanism of action, the nurse would understand that the daughters' request is based on their belief and desire for their father's condition to improve. The nurse would incorporate this understanding in discussions with the daughters about their father's condition. In addition, the nurse would also begin assisting the daughters to "let go" and begin the grieving process should the patient's condition remain unchanged, even after the acupuncture.

FIGURE 29-9. A chiropractic health care professional provides an adjustment. (*Source: Photo by Microgen/Shutterstock.*)

Chiropractic Health Care

Chiropractic health care is a profession that focuses on the relationship between the body's structure—mainly the spine—and its functioning (NCCIH, 2019c). Chiropractic practitioners primarily perform adjustments (manipulations) to the spine or other parts of the body with the goal of correcting alignment problems, alleviating pain, improving function, and supporting the body's natural ability to heal itself (Fig. 29-9). The NCCIH reports that most research on chiropractic health care has focused on spinal manipulation (NCCIH, 2019c). Spinal manipulation appears to benefit some people with low-back pain and may also be helpful for headaches, neck pain, upper- and lower-extremity joint conditions, and whiplash-associated disorders. Chiropractors may combine the use of spinal adjustments and other manual therapies with several other treatments and approaches, such as exercise and nutritional counseling (NCCIH, 2019c).

Doctors of chiropractic medicine (DC) are licensed and attend 4 years of chiropractic school after prerequisite undergraduate coursework and pass a national licensing exam. The types of services chiropractors are allowed to provide vary from state to state (NCCIH, 2019c). At this time, most chiropractic treatment is conducted on outpatients. A good understanding of chiropractic medicine will allow you to answer patients' questions and ask questions about a patient's current treatments. This knowledge also helps you to be able to refer patients asking questions about chiropractic medicine to reliable sources of information.

Recall **Brian Legett**, the patient with chronic back problems who has experienced little relief and is asking about seeing a chiropractor. When responding to Mr. Legett, the nurse would need to explain the underlying principles of chiropractic science. In addition, the nurse, in conjunction with other health care team members involved in the patient's plan of care, would need to review the patient's history thoroughly to identify (if possible) the underlying cause of his back problems and the various treatments attempted. This review would be important in determining if a referral to a chiropractor would be appropriate.

Aromatherapy

Aromatherapy is the use of essential oils of plants as a therapy to improve physical, emotional, and spiritual well-being

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

(Fontaine, 2019). The fragrance of these oils is believed to ultimately affect the very sensitive amygdala of the limbic system in the brain, where emotional memories are stored and released (Johns Hopkins Medicine, n.d.). Laboratory and animal studies have shown that certain oils have antibacterial, antiviral, antifungal, calming, and energizing effects. Essential oils can be absorbed by the body through in halation and topical applications (Helming et al., 2022). Aromatherapy practices have been utilized in the management of pain, sleep disorders, anxiety, depression, nausea and vomiting, and increased general well-being (Dilek & Necmiye, 2020). Commonly used essential oils in a health care setting are ginger for nausea and lavender for insomnia (Fontaine, 2019). Essential oils vary in quality and potency depending on the manufacturing processes. If specific essential oils are approved for use in an inpatient setting, provide education on these oils. Some people are highly sensitive to strong fragrances, particularly concentrated essential oils. This might preclude their use in some patient settings.

Certification in Aromatherapy for health professionals is available. Standards for professional aromatherapy education are set by the National Association for Holistic Aromatherapy (n.d.b).

Energy-Healing Therapies

Energy-healing therapies include many diverse practices, with a fundamental underlying assumption that all life is sustained by universal life energy that moves freely within and without a person's being (Helming et al., 2022). Energy-healing therapy techniques are based on the belief that this primary life force can be influenced and thus contribute to physiologic healing. These techniques involve channeling healing energy through the hands of a practitioner into the patient's body to restore a normal energy balance and, therefore, health (Clarke et al., 2015). Energy-healing therapies are used in treating a wide variety of ailments and health problems and may often be used with other CHAs as well as conventional medical treatments (Clarke et al., 2015).

THERAPEUTIC TOUCH

Therapeutic touch (TT) is the process of energy exchange; practitioners focus on healing by use of their hands on or near the body with the intent to help or heal (Bagci & Cinar Yucel, 2020). The TT process consists of centering, assessing the energy field, and rebalancing the field using modulation, *unruffling*, and other techniques (Krieger, 1993).

TT uses four primary scientific premises (Krieger, 1993, pp. 12–13):

. All the life sciences agree that, physically, a human being is an open energy system.
. Anatomically, a human being is bilaterally symmetrical.
. Illness is an imbalance in a person's energy field.
. Human beings have natural abilities to transform and transcend their conditions of living.

TT has been used to manage pain and anxiety as well as other symptoms (Bagci & Yucel, 2020). Registered nurses can become credentialed in TT (TTIA, 2003).

HEALING TOUCH

Healing touch (HT) uses gentle intentional touch to assist in balancing physical, emotional, mental, and spiritual well-being (Healing Beyond Borders, 2020). The goal of HT is to restore wholeness through harmony and balance, enhancing the person's ability to self-heal (Hausladen Foley et al., 2016). Treatment involves the health care provider placing their hands either on or slightly above the body to assess for disturbances in the energy field, then working with the energy fields (auras) and energy centers (chakras) to clear and balance the energy (Healing Beyond Borders, n.d.). Certification in HT for people of various backgrounds is available through several Healing Touch organizations.

SOUND HEALING

Sound is an ancient form of healing. Examples include the central importance of drum and flutes for American Indians and Tibetan singing bowls. Sound, using the vibrational energy of tones, music, chants, song, and a variety of sound-producing instruments, is used to promote relaxation and healing (Fontaine, 2019). Music has been used to help patients relax, to increase sleep quality (Kavurmaci et al., 2020), decrease anxiety (Langer Bro et al., 2019) is increasingly used in hospice to comfort the dying. Music can be used to promote positive outcomes in several ways. Patients can listen to their favorite music prior to surgery or other stressful events, during imagery, and while relaxing. Music is frequently played in operating rooms with positive effects on the performance of the surgical team (Rastipisheh et al., 2019), and harp or piano music is played in patient lounges and lobbies. Music is also implemented to improve the quality of life for patients with communication impairment, such as later-stage dementia, and increase nonverbal communication (Clare et al., 2020).

Think about **Brian Legett**, the man with chronic back pain described at the beginning of the chapter. Based on an assessment of the patient's likes and dislikes, the nurse might suggest music therapy as a means to help Brian relax and reduce his discomfort.

Manipulative and Body-Based Practices

This group of therapies includes therapeutic massage—an assortment of techniques that involve manipulation of soft tissues of the body through pressure and movement, as well as a variety of techniques such as Rolfing, shiatsu, Feldenkrais method, Alexander technique, myofascial release (MFR), and others. The goal is to break up tension held in body structures, promote communication between mind–body structures, promote detoxification, and generally improve body functioning. Some of these therapies can be painful while they work to oxygenate tissues, break up lymphatic congestion, release muscle tightness, and promote circulation. These therapies require specialized educational preparation and are particularly useful in rehabilitation or health-promotion settings.

Natural Products

Botanical agents (herbs) and nutritional supplements are chemical compounds that are ingested with the hope of achieving a therapeutic goal. They are becoming increasingly popular with consumers, who can buy many of these preparations over the counter (OTC) or from company distributors. Currently, dietary supplements (which include herbs and nutritional supplements) are considered foods, thus manufacturers need to follow FDA labeling requirements (FDA, 2019). Some product sample analyses have revealed inconsistencies in the amount of active ingredients. The National Institutes of Health Office of Dietary Supplements (ODS) works to strengthen knowledge and understanding of dietary supplements and provides dietary supplement fact sheets for both health professionals and consumers (ODS, n.d.a). These fact sheets and other up-to-date information regarding dietary supplements, including consumer protection updates from the FDA may be accessed from this site at https://ods.od.nih.gov/factsheets/list-all/ (ODS, n.d.b).

Botanicals (Herbal Products) and Nutritional Supplements

Some consumers and practitioners are attracted to herbs because they are "natural" plant products, which may be perceived as more compatible with the body than manufactured pharmaceutical agents. In fact, some pharmaceutical agents (e.g., digitalis) were first produced as natural products derived from plants and now are produced chemically. In many countries, herbal products are regulated and available through the primary health care system. In Germany, for example, the Federal Institute for Drugs and Medical Devices Commission E reviews scientific data and establishes prescriptive standards for herbs and plant products used for healing (NCI, n.d.b). In the United States, the FDA classifies herbs as a food and not a drug, falling under the category of dietary supplements (MFMER, 2017a). This is important because herbs are not regulated for quality and potency as drugs are, and herbal formulas can be sold without being studied to see if they are helpful or harmful (MFMER, 2017a).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 29-10. Herbs may be used as part of a treatment plan for patients who choose a whole medical system. (*Source:* Hood, L. [2018]. Leddy & Pepper's professional nursing [9th ed.]. Wolters Kluwer.)

Many whole medical systems use herbs as part of their treatment system for disease and reduction of symptoms (Fig. 29-10) (whole medical systems are discussed in the Other Complementary Health Approaches section). For example, echinacea and goldenseal (separately or in combination) may be used for infections, and ginkgo biloba is used to dilate blood vessels and reduce symptoms of memory loss and mental confusion (Fontaine, 2019).

Nutritional (dietary) supplements are chemical compounds that contain ingredients (vitamins, minerals, enzymes, amino acids, essential fatty acids) believed to promote health. These products have a wide range of safety and effectiveness.

Extensive specialized education is required before a nurse can be competent to advise patients on the use of herbs and supplements. However, as increasing numbers of patients are using herbs and supplements, nurses need to be aware of the various products available and provide education to patients to ensure safety with their use. For example, some herbs and/or supplements may interact with prescribed medications patients are taking. Ginkgo biloba, used by people to improve memory, affects platelet function and should not be used concurrently with other antiplatelet drugs and anticoagulants (MFMER, 2017b). The herb kava, used by patients for anxiety, has been linked to serious liver damage (Mayo Clinic, 2019). Women who are pregnant or nursing and children are particularly at risk and should be especially cautious about using herbal supplements either alone or in mixtures. Many supplements have not been well tested for safety in pregnant women, nursing mothers, or children (ODS, 2020). Herbals/health supplements should not be given to a child unless recommended by their health care provider (ODS, 2020). Teaching Tips 29-1 (on page 900) provides important patient education information related to herbs and supplements.

Medical Cannabis

Multiple products from the cannabis plant species have been promoted as "natural" products to alleviate numerous symptoms and increase wellness (Long, 2020; Trentham, 2019b). Patients are increasingly using prescribed medical marijuana and cannabidiol products that are available without a prescription to treat their conditions (Brown, 2020). However, despite marketing for the treatment of a variety of conditions, conclusive evidence regarding safety and efficacy of cannabis for therapeutic purpose is, for the most part, lacking (Dill & Kurkowski, 2020). Therapeutic uses for cannabis or cannabinoids include for antiemetic effects in chemotherapy-induced nausea and vomiting, chronic pain in adults, multiple sclerosis–related spasticity, and reduction of seizure frequency associated with severe epilepsy (National Academies of Sciences, Engineering, and Medicine, 2017; U.S. FDA, 2018b). Nurses need to have an understanding of the endocannabinoid system and understand cannabis pharmacology and the research associated with use of these products (Brown, 2020; NCSBN, 2018). Nurses must also remain aware of the current legal status of cannabis products

and be able to answer patients' questions and provide patients accurate information related to their safety and effectiveness (Brown, 2020; NCSBN, 2018).

The marijuana components tetrahydrocannabinol (THC) and cannabidiol (CBD) are the most commonly known compounds of the marijuana (cannabis) plant. THC is the active psychoactive compound in marijuana and is what is tested for in a urine drug screen. The biologic effects of cannabinoids are mediated by cannabinoid (CBI) receptors, located throughout the body, and especially focused near the nervous system, and are part of the endocannabinoid system in the body (Benson, 2019; Long, 2020). The endocannabinoid system is an internal regulatory system that functions to maintain homeostasis and equilibrium (Benson, 20109; Long, 2020; Meletis, 2020; Theisen & Konieczny, 2019). The most common and well-studied CBI receptors include CB1 and CB2 (Theisen & Konieczny, 2019). CB1 receptors are predominantly found in the central and peripheral nervous systems as well as other organs of the body and, when activated, can help alleviate anxiety, stress, pain, and inflammation (Theisen & Konieczny, 2019). CB2 receptors are concentrated in the peripheral immune cells as well as in the central and peripheral nervous systems and the lungs and, when activated, can help alleviate inflammation (Theisen & Konieczny, 2019). In addition to CBI receptors, this system also consists of ligands and enzymes that regulate sleep, pain perception, memory, mood, and appetite. The receptors can be stimulated by endogenous cannabinoids as well as plant-derived and synthetic cannabinoids (Theisen & Konieczny, 2019). The ligands act as chemical messengers to stimulate cannabinoids to interact at the receptor sites, and the enzymes break down cannabinoids after they have completed their function (Theisen & Konieczny, 2019). Cannabinoids are chemical compounds that can influence the cannabinoid receptors and promote the release of neurotransmitters. Tetrahydrocannabinol (THC) and CBD are the most abundant cannabinoids (Theisen & Konieczny, 2019).

Teaching Tips 29-1

USING HERBS AND SUPPLEMENTS

Teaching Tip	Why Is This Important?
Get information from knowledgeable and reliable sources.	Advertising media and many sources on the Internet frequently seek primarily to sell the product, not educate the consumer.
Buy products that are produced by reputable companies and include label logos that identify dietary supplements and herbals that have been tested for ingredient quality and contaminants.	Since this industry is not regulated, contamination and inconsistency in the amount of product sometimes occur.
Whenever possible, buy single products.	If the product contains several ingredients and you have a reaction or positive response, you won't know which ingredient was the causative agent.
Follow the label instructions and monitor for adverse effects.	Herbal remedies and supplements can be toxic in higher-than-recommended doses.
Become knowledgeable about the product and your reason for using it.	Consumers who initiate any type of self-care tend to make better decisions if they are well informed.

Source: Modified from Helming, M. A. B., Shields, D. A., Avino, K. M., & Rosa, W. E. (Eds.). (2022). Dossey & Keegan's Holistic nursing. A handbook for practice (8th ed.). Jones & Bartlett Learning; National Center for Complementary and Integrative Health (NCCIH). (2019). *Using dietary supplements wisely*. https://www.nccih.nih.gov/health/using-dietary-supplements-wisely#hed6

Marijuana is listed in the Schedule I of the federal Controlled Substances Act because of the psychoactive effects of THC and the potential for abuse. The U.S. Drug Enforcement Administration (DEA) considers all cannabinoids, including marijuana and CBD, a Schedule I drug and they remain illegal under federal law (Benson, 2019; Trentham, 2019a), with one exception. FDA-approved drugs that contain CBD derived from cannabis and no more than 0.1% THC have been placed in Schedule V (U.S. DEA, 2018). Hemp is regulated by the U.S. Department of Agriculture, and, if it is produced in a manner consistent with federal and state regulations and the THC content is negligibly low (not more than 0.3% THC), is considered legal (Agriculture Improvement Act of 2018, 2018). State laws regarding any of these substances vary and range from making it legal for prescribers to recommend CBD oils for certain conditions, limiting the allowable THC content in CBD oil, permitting clinical research, and making or not making provisions for legal sale or purchase of CBD (Bemben, 2019).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

The FDA has approved a new drug class of medications called cannabinoids (Brown, 2020). FDA-approved cannabinoids include an oral CBD-based drug (Epidiolex), which has been shown to reduce the frequency of seizures when compared with a placebo and has been approved to treat severe forms of epilepsy (Brown, 2020; U.S. FDA, 2018b). Dronabinol is a synthetic cannabinoid approved to treat chemotherapy-induced nausea and vomiting and anorexia and weight loss secondary to AIDS (Bemben, 2019). Nabilone is another synthetic cannabinoid similar to THC and is approved for refractory chemotherapy-induced nausea and vomiting (Bemben, 2019). FDA regulations indicate that products that contain THC or CBD cannot be sold as dietary supplements (Gottlieb, 2018).

MARIJUANA

Marijuana plants contain high levels of THC and lower levels of CBD (Trentham, 2019b). THC is the most abundant cannabinoid in the cannabis plant. The FDA has not approved the plant marijuana for the treatment of health problems (Trentham, 2019b). Fifteen states, two territories, and the District of Columbia have legalized medical and recreational marijuana (ProCon, 2020b). Another 34 states and 2 more territories have legalized medical marijuana only to treat certain medical conditions (ProCon, 2020b).

Medical marijuana is available in several forms for consumption, dictated by state law. Available forms may include pills containing oil to be swallowed and digested; extracts that are inhaled or vaporized; liquids and tinctures for use under the tongue or as an oral spray; topical gels, creams, and ointments for localized effect; patches for transdermal absorption; and flowers/dry leaf to be consumed through vaporization. THC produces euphoric, psychoactive effects that influence mood, consciousness, and behavior. Side effects are dose dependent and may include hypotension, hallucinations, tachycardia, central nervous system depression, euphoria, dizziness, drowsiness, somnolence, confusion, new or worsening nausea and vomiting, and seizures and can lead to substance use disorder (Theisen & Konieczny, 2019).

The use of substances with THC to treat certain health problems or for recreational use could be legal based on State law but may still result in violation of the law (Trentham, 2019b). For example, persons employed in safety sensitive positions, such as nurses, in which use of marijuana may negatively impact the work performance and constitute a threat to health or safety, cannot test positive for marijuana or its constituents. A positive test may result in disciplinary action by an employer. Many state and professional regulations do not differentiate between consumption of marijuana for medical purposes while not working and use during work hours/employment (Trentham, 2019b).

CANNABIDIOL

CBD is the second most active ingredient and a natural component found in marijuana plants. CBD is one of many chemicals in the cannabis plant and is also a compound found in hemp (Trentham, 2019b). It is derived from the stalks, leaves, and buds of the hemp plant (Trentham, 2019b). CBD is a mood-altering substance (Theisen & Konieczny, 2019) but is considered a nonpsychoactive chemical (Long, 2020; Trentham, 2019b). It does not produce a "high" or euphoric effect (Brown, 2020). There is a lack of large-scale clinical trials showing the efficacy of CBD as well as evidence-based recommendations and in-depth understanding of risks and benefits (Hande, 2017; Whiting et al., 2015, as cited in Bonn-Miller et al., 2017). Seventeen states have laws specifically addressing CBD (Bemben, 2019; ProCon, 2020a).

There is growing consumer demand for CBD constituents of the cannabis plant due to purported medicinal benefits (Whiting et al., 2015, as cited in Bonn-Miller et al., 2017). CBD has been shown to improve mood by decreasing anxiety and depression and is effective for treating nausea and vomiting, seizures, and pain (Theisen & Konieczny, 2019). CBD is being studied as a treatment for other conditions, including chronic pain, Parkinson disease, schizophrenia, diabetes, multiple sclerosis, irritable bowel syndrome, movement disorders due to Tourette syndrome, posttraumatic stress disorder, and sleep disorders, but research supporting benefits remains limited (Bauer, 2018; Long, 2020; NCCIH, 2019h). Consumers report use of CBD for potential therapeutic effect, either alone or in combination with other therapies, in treating seizure disorders, psychotic symptoms, anxiety, depression, inflammation, cancer, cardiovascular diseases, neurodegeneration, symptoms of multiple sclerosis, sleep disorders, and chronic pain (Benson, 2019; Carroon & Phillips, 2018). Side effects are dose dependent, including dizziness, anxiety, diarrhea, jitteriness, decreased appetite, hepatocellular injury, dry mouth, fatigue, somnolence, sedation, nausea, vomiting, changes in appetite or mood, and suicidal ideation (Bemben, 2019; Theisen & Konieczny, 2019; Trentham, 2019b).

CBD is available in several forms. CBD capsules, pills, and gummies are available for oral consumption with absorption via the GI tract (Benson, 2019). Oral products allow for convenient dosing, with slow absorption (Brown, 2020). CBD is also suspended in oil or alcohol (tincture), which is placed under the tongue with a dropper and absorbed via capillaries. This results in quicker absorption and more rapid effects (Benson, 2019). CBD is also available as a vaporization liquid for inhalation using an e-cigarette, with quick absorption from the lungs into the bloodstream (Benson, 2019; Brown, 2020). This route of administration is associated with damage to the lungs (Brown, 2020). Topical CBD is available in creams and lotions. Administration via this route results in localized effects but has been associated with localized skin reactions (Brown, 2020).

There is a lack of precision in product labeling that may contribute to a false sense of safety (Trentham, 2019a). There are few studies to support CBD products obtained without a prescription to treat any medical conditions (Brown, 2020). The CBD products that are sold in the United States are not regulated by the FDA. Discrepancies between federal and

state cannabis laws result in inadequate regulation and oversight leading to inaccurate labeling of some products. Most CBD products claim to have under 0.3% THC, classified as hemp, but a lack of regulation in the manufacturing process, consistent dosing, testing standards, and oversight may also contribute to unreliable THC levels (Bonn-Miller et al., 2017; Trentham, 2019b). A 2017 study by Bonn-Miller et al. examined 84 products from 31 companies available via online retail that included CBD content on the packaging. A blind analysis of cannabinoid content identified a wide range and inconsistent CBD concentrations: 26% contained less CBD than labeled; 21% contained THC; and 43% were underlabeled (CBD concentrations were higher than listed on the product). The authors concluded the findings highlight the need for additional monitoring of products sold on the Internet and for manufacturing and testing standards, as well as oversight of medicinal cannabis products (Bonn-Miller et al., 2017).

CBD Safety

Most patients tolerate CBD products (Brown, 2020). However, there is a lack of quality scientific studies on the use and effects of CBD, and the long-term effects of using CBD products are unknown at this time, as there have been no long-term studies to date (Brown, 2020). CBD use may cause increased activity of anticoagulants (Brown, 2020); increased serum concentrations of selective serotonin-reuptake inhibitors, antipsychotics, beta-blockers, opioids, tricyclic antidepressants, benzodiazepines, antihistamines, some statins, macrolides, and antiretrovirals (Fugh-Berman et al., n.d.); and increased liver enzymes (Fugh-Berman et al., n.d.). There is also some concern for unreliability of the purity of CBE products; concentrations of CBD oil vary widely from brand to brand and bottle to bottle within brands (Trentham). Companies use different CBD sources, extraction methods, and production techniques, and not all resulting products are equal (Trentham). Some state regulations allow for up to 5% THC in CBD oil (Trentham, 2019b). Patients and health care providers should be aware that consumption of CBD oil or products with CBD oil may result in a positive urine drug screen for THC; consumption of CBD with higher concentrations will result in a positive urine test for THC (Brown, 2020; Trentham, 2019b).

HEMP OIL

Hemp oil is derived from industrial hemp, a variety of cannabis plant species, which has a lower concentration of THC compared to marijuana (Trentham, 2019b). The amount of THC in hemp is to be less than 0.3%, in order to be sold legally (Andres, 2019; Trentham, 2019b). Hemp oil is low in saturated fat and high in antioxidants, vitamin E, and omega-3 and -6 fatty acids and may be used as an ingredient in cooking. Manufacturers of shampoos, soaps, and body lotions may include hemp oil as an ingredient. Patients and healthcare providers should be aware that consuming hemp foods can cause positive results in urine drug screening testing for THC (Trentham, 2019b).

PATIENT EDUCATION

As with any health-related issue, patient education related to the use of cannabis and CBD products is an important nursing intervention. Patients need to be aware that CBD products available online and OTC without prescription are not regulated and not proven to treat any medical condition (Brown, 2020). Patients should be encouraged to consider products with full disclosure regarding the ingredients of the product, to carefully examine product labels (Bensen, 2019; Epstein, 2020), and review the certificate of analysis (COA) for any OTC product (Theisen & Konieczny, 2019). Patients should look for products with certification from outside agencies, such as the National Science Foundation International (Benson, 2019). Discussions with patients should include information about cannabis, marijuana, and CBD safety, effectiveness, and potential side effects (Brown, 2020; Hande, 2017). It is also important to identify all medications (prescription and OTC) and supplements the patient is using to identify and discuss potential drug interactions (Brown, 2020). Patient education should also address the potential for positive urine drug screening and related consequences, as indicated (Brown, 2020).

Nurses frequently care for patients who use or who are considering use of therapeutic cannabis products and must have adequate knowledge about these products and clinical implications to better serve patients. Theisen and Konieczy (2019) suggest nurses can help patients make smart decisions by educating themselves. As more patients decide to explore cannabis as a CHA, nurses may be faced with making clinical judgments to balance promoting and safeguarding personal integrity and respecting the values and preferences of patients and others. Refer to the Thoughtful, Person-Centered Practice: Challenging Topics Medical Cannabis to work through one possible patient care scenario.

Thoughtful, Person-Centered Practice: Challenging Topics

Medical Cannabis

Many controversial issues make it challenging to know how to respond as a professional nurse in select scenarios. Often, the nurse's personal and/or professional values may conflict with options desired by patients, families, employers, and communities. Not infrequently, nurses have to make clinical judgments balancing promoting and safeguarding personal integrity and respecting the values and preferences of patients or others.

Read the scenario below and see if you can articulate what you believe, why you believe this, and how these beliefs are likely to inform the decisions you make and your behavior, especially when you are confronted with competing obligations. Based on Tanner's Clinical Judgment Model (2006), consider reflection-in-action and reflection-on-action (Nielson, Stragnell, & Jester, 2007):

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Reflection-in-Action: As you read, consider what the nurse is thinking in the moment—What happened? How did the patient, family/caregiver, and or healthcare provider respond? What did the nurse do next?

Scenario

You are a camp nurse and administering the children's prescribed medications is one of your responsibilities. On Johnny's first day, he hands you a bottle hand-labeled as "Cod Liver Oil," which his mother wants administered by mouth, twice a day. You contact the mother and tell her you need a physician's order to administer anything, even over-the-counter or holistic medicine. She sends you back the child's physical with clearly photo-shopped instructions to give two droppers full. You call the physician who did the physical to clarify the order, and he confirms that he did not write it. When you inform the mother, she is irate that you violated her privacy by contacting the physician. Suspicious about the mother's behavior, you smell the bottle and suspect it is cannabis based.

Effective Noticing (Cues)

1. What did you notice about the situation initially? What information/observations are significant? What information deviates from what is expected/normal/usual?

Scenario

When you call the mother back, she admits that the "Cod Liver Oil" is really a full-spectrum cannabidiol (CBD) oil that she had been administering to her son twice daily for his attention-deficit/hyperactivity disorder (ADHD). You think that CBD is a schedule 1 controlled substance, but you are not sure; you know that different forms of cannabis have been legalized on both state and federal levels. You have kept your manager informed, and she seems more concerned about placating the mother than promoting Johnny's well-being—or yours! Do you administer the oil to Johnny? Is administering this drug within your scope of practice?

You want to talk with Johnny to learn what he knows about the "cod liver oil," but his mother tells you that she does not want him to know that he is taking CBD oil. She was adamant that Johnny be told it is a vitamin supplement.

You wonder if you have an obligation to report this mother to child protective services.

Effective Interpreting

1. How would you prioritize this data? What other assessment data, evidence and/or information would you need to consider the situation? How would you obtain this additional information?
2. What do you think about this situation? Consider personal and previous nursing experiences that you have had and formal knowledge (physiology, psychology, communication skills) that may be of assistance in providing care in this situation.
3. Once the nurse suspects that the "cod liver oil" is actually some form of cannabis, she is less certain of how to proceed because she has never been in a situation like this before. What sort of "fact finding" would you recommend and what resources can you tap? How could you best learn what you need to know about the oil; your scope of practice and legal obligations about administering a cannabis-based oil; your ethical obligations to protect the patient, especially if it turns out, as it did in this case, that your initial research showed that children with ADHD do well with stimulants but not with depressants, which the oil was?

Now, see if you can articulate what you believe, why you believe this, and how these beliefs are likely to inform the decisions you make and your behavior, especially when you confronted with competing obligations.

Effective Responding

4. How would you describe the obligations you have in this scenario to your patient and his mother, to yourself, and to your employer?
5. If you cannot fulfill each of these obligations, how will you prioritize them? What basis/rationale do you use for prioritization? Remember that the ANA *Code of Ethics for Nurses* reminds us that "the nurse's primary commitment is to the patient," while at the same time states that "the nurse owes the same duties to self as to others, including the responsibility to promote health and safety, preserve wholeness of character and integrity, maintain competence, and continue personal and professional growth.
6. What are a nurse's reporting obligations when a child or other vulnerable party is at risk? What resources will you consult to learn more about this? Is your duty to report the mother's behavior trumped by another consideration/obligation?

Effective Reflecting

7. Which statement below best captures your beliefs?

a. Parents should be able to make decisions for their children and a nurse does not have the right to challenge these decisions.

b. Parents do not have unlimited rights over their children. If I believe their decisions are likely to harm a child, I have an obligation to advocate for the well-being of the child.

How will your belief inform your response in this scenario?

8. Whether you decide to administer the oil as directed by the boy's mother and your employer or refuse, how might you use reflective practice to evaluate your decision so you can respond more confidently in similar situations in the future? What criteria will you use to evaluate a good response?
9. What personal attributes and competencies are most likely to lead to a good response?

Reflection-on-Action

Then look back at the nurse's decisions and reflect on your learning—how did your knowledge and/or skills expand based on this scenario? What attitude, value, or belief shifts did you experience (if any) after reading this scenario? What would you do differently if you were in this situation? What more do you need to know to be able to manage this or a similar situation in the future?

Nielson, A., Stragnell, S., & Jester, P. (2007). Guide for reflection using the Clinical Judgment Model. *Journal of Nursing Education, 46*(11), 513–516. https://doi.org/10.3928/01484834-20071101-06

Tanner, C. A. (2006). Thinking like a nurse: a research-based model of clinical judgment in nursing. *Journal of Nursing Education*, *45*(6), 204–211. https://doi.org/10.3928/01484834-20060601-04

Nutritional Therapy

The eating habits of people in the United States are being scrutinized because of the alarming increase in obesity, particularly in children, and chronic illnesses in all age groups. A diet consisting of prepared and processed foods and large amounts of meat, dairy products, and sugar has been associated with various diet-related chronic diseases and unfortunately represents the dietary habits of many Americans (U.S. Department of Health and Human Services and U.S. Department of Agriculture, 2020). People with a variety of credentials have endorsed many eating plans that purport to address these health problems. The diversity of these approaches is understandably very confusing to the consumer. An examination of these popular diets is beyond the scope of this book. Holistic nutrition approaches health and healing from a whole-person, individualistic perspective, providing advice on how to improve diet, lifestyle, and attitude to promote optimal health (NANP, n.d.). This belief has been a cornerstone of holistic nutritional approaches for centuries in traditional Chinese medicine (TCM) and Ayurvedic systems (discussed in the next sections). Many of these approaches are endorsed by naturopathic practitioners (naturopathy is discussed on page 905).

Other Complementary Health Approaches

Whole medical systems (or alternative medical systems) are other CHAs and consist of a philosophy and theory about health and illness along with specific types of treatment. These systems have developed independently from allopathic medicine and are generally culturally based. Ayurveda, TCM, shamanism (which includes native traditions), homeopathy, and naturopathy are examples of whole medical systems.

Ayurveda

Ayurveda originated in the ancient civilization of India and is considered one of the world's oldest medical systems (NCCIH, 2019e). The aim of Ayurvedic medicine is to integrate and balance the body, mind, and spirit (Fontaine, 2019). Key concepts include universal interconnectedness among people, their health, and the universe; and the body's constitution and life forces (Helming et al., 2022). Ayurvedic practitioners prescribe individualized treatments that include herbs, metals, minerals, and other materials; diet and exercise; and lifestyle recommendations (NCCIH, 2019e). Ayurvedic products are regulated as dietary supplements in the United States, and some have the potential to be toxic due to the present of metals (NCCIH, 2019e).

Special considerations may be necessary for patients who want to continue their Ayurvedic program while hospitalized. For example, some people may have special dietary (e.g., vegetarian) needs, some may need time set aside for self-care such as meditation, and some may desire to continue taking an herbal supplement. All precautions related to herbal and pharmaceutical interactions should be followed when using Ayurvedic herbal preparations.

Traditional Chinese Medicine

Underlying the practice of **traditional Chinese medicine (TCM)** is a unique view of the world and the human body that is different from Western medicine concepts. This view is based on the ancient Chinese belief of a natural order in the universe and an interconnectedness between the body and the cosmos, with a search for balance and harmony; a perception of humans as a small part of the larger surrounding universe—interconnected with nature and subject to its forces. The human body is regarded as an organic entity in which the various organs, tissues, and other parts have distinct functions but are all interdependent. In this view, health and disease relate to balance of the functions, as well as a balance of yin and yang energy (two opposing, yet complementary forces that shape the world and all life) (Cancer

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Research UK, 2018).

The goal of TCM is health promotion and quality of life, with an emphasis on the patient, not the illness (Fontaine, 2019). TCM practitioners use various mind and body practices, such as acupuncture and tai chi, as well as herbal products to address health problems (NCCIH, 2019b).

Shamanism

Shamanism is the oldest of all healing therapies concerned with the nature of creation, the natural flow of life, and with showing respect to our fellow creatures and one another (Fontaine, 2019). Shamanism developed in widely separated areas of the world, including North, Central, and South America, Africa, Australia, Indonesia, Malaysia, Bali, Tibet, Korea, Siberia, and across Europe (Fontaine, 2019). In shamanism, illness and other forms of distress are thought to originate in the spirit world (Vadala, 2019). The shaman or medicine man/woman possesses the ability to access the spirit world, which is done on behalf of people or the community, and return to "ordinary reality" with information on the proper treatment (Society for Shamanic Practice, n.d.). Particular emphasis is on the classic shamanic journey, one of the most remarkable visionary methods used by humankind to explore the hidden universe otherwise known mainly through myth and dream. Treatment may consist of retrieving lost soul energy, restoring the person to the right relationship with the spirit world, and treating symptoms (Andrews et al., 2020). General healing techniques involve native plants and herbs, animals, rituals, ceremonies, and purification techniques. In the United States, shamanic healing is gaining in popularity as Americans turn back to the old cultures for help and guidance in finding a better balance with nature and with themselves (Fontaine, 2019).

Homeopathy

Homeopathy is a medical system that was developed in Germany more than 200 years ago (NCCIH, 2018). The allopathic approach to dealing with illness is frequently to suppress symptoms; for example, acetaminophen can be given to reduce a fever. In contrast, homeopaths believe that when symptoms are suppressed in this manner, the condition "goes deeper" into the body, making it ultimately more difficult to cure. Supporters of homeopathy point to two unconventional theories (NCCIH, 2018):

- "Like cures like": The notion that a disease can be cured by a substance that produces similar symptoms in healthy people.
- "Law of minimum dose": The notion that the *lower* the dose of the medication, the *greater* its effectiveness. Many homeopathic remedies are so diluted that no molecules of the original substance remain.

Homeopathic remedies are derived from substances that come from plants, minerals, or animals, and include things such as red onion, arnica (mountain herb), crushed whole bees, white arsenic, poison ivy, belladonna (deadly nightshade), and stinging nettle (NCCIH, 2018). Homeopathic remedies are often formulated as sugar pellets to be placed under the tongue; they may also be in other forms, such as ointments, gels, drops, creams, and tablets. Treatments are "individualized" or tailored to each person—it is not uncommon for different people with the same condition to receive different treatments (NCCIH, 2018). There is little evidence to support homeopathy as an effective treatment for any specific condition (NCCIH, 2018). Although people sometimes assume that all homeopathic remedies are highly diluted and therefore unlikely to cause harm, some products labeled as homeopathic can contain substantial amounts of active ingredients, thus could cause side effects and drug interactions (NCCIH, 2018).

Focused Assessment Guide 29-1

HOLISTIC CARE

Factors to Assess	Questions and Approaches
Stress	What measures does the patient use to reduce stress? If the patient wants to continue a meditation, relaxation, or imagery practice while receiving care, explore ways in which that can be accomplished.
Music/sound preferences	What preferences does the patient have for music or environmental sounds (e.g., ocean waves, birds) either while meditating or relaxing? Music could be provided by the patient if preferred music is not available.
Diet	What dietary preferences does the patient have (e.g., vegetarian, no processed foods)? Communicate these preferences to nutritional services.
Environmental sensitivity	Is the patient sensitive to environmental odors or fragrances? If so, can an air purifier be brought to the room?
Use of herbs and supplements	Is the patient taking any herbs or supplements as directed by a CHA practitioner or purchased over the counter? If so, obtain the names of the herbs/supplements, dosages, and reasons for their use. If these substances are in the patient's possession, follow applicable institutional policies.
Use of CHA health care provider	Is the patient planning to use a primary CHA provider while receiving allopathic care? If so, convey appropriate information to the primary allopathic provider.

Naturopathy

Naturopathy has evolved from traditional practices and health care approaches popular in Europe during the 19th century (NCCIH, 2017). Naturopaths believe that health is a dynamic state of being that provides abundant energy for people to deal with life in our complex society. Naturopathic medicine holds that the body innately knows how to maintain health and heal itself (Fontaine, 2019). The naturopathic provider's role is to support and restore the body using techniques and medicines that are geared to strengthen the body's own healing ability (Fontaine, 2019). Naturopathic practitioners use many different treatment approaches, including dietary and lifestyle changes, stress reduction, herbs and other dietary supplements, manipulative therapies, practitioner-guided detoxification, psychotherapy, and counseling (NCCIH, 2017). In the United States, naturopathic medicine is practiced by naturopathic physicians, traditional naturopaths, and other health care providers who also offer naturopathic services (NCCIH, 2017, para 3).

NURSING IMPLICATIONS OF COMPLEMENTARY HEALTH APPROACHES

The development of CHAs continues to be a market-driven and, in some respects, a patient-driven phenomenon. Many patients/consumers are unsatisfied with allopathic treatments and are turning to CHAs for relief of symptoms and healing. Since health care currently operates on a business model, it is probable that more CHAs will become available to deal with real or perceived market needs. Third-party payers do not cover many of these therapies, which means that consumers must pay out of pocket for them. In addition, government and professional groups do not regulate most of the therapies. Because of this lack of regulation, there can be inconsistencies among the preparation and care provided by practitioners.

Nursing is expanding its knowledge base to include information that addresses CHAs. For example, pharmacology courses in schools of nursing frequently include information on herbs. Certifications in basic holistic nursing for nurses with a baccalaureate degree and in advanced holistic nursing for nurses with a master's degree are available through the AHNCC. It is expected that CHAs will become a larger part of practice for nurses. See the accompanying PICOT in Practice on page 906. There is a great opportunity for nurses to expand their practice to meet existing patient needs as well as to promote health. See the Focused Assessment Guide 29-1: Holistic Care for identification of areas in which a holistic nurse can approach patient care.

Patient education about CHA is essential. Patients and the public need to know about the safe and effective use of CHA. Numerous resources exist to educate health care professionals and the public. The NCCIH health topics page is always a good place to start. The NCCIH encourages patients to talk with health care providers about their use of CHAs (NCCIH, 2020c). Box 29-3 (on page 906) outlines tips nurses can use with patients from the NCCIH to help patients begin a conversation with their health care provider. The National Cancer Institute's Office of Cancer Complementary and Alternative Medicine (OCCAM, 2013) provides a valuable teaching resource entitled *Talking about Complementary and Alternative Medicine with Health Care Providers: A Workbook and Tips*. This resource is available for patients and professionals on their website at https://cam.cancer.gov/health_information/talking_about_cam.htm.

PICOT in Practice

ASKING CLINICAL QUESTIONS: ACUPUNCTURE/ACUPRESSURE

Scenario: You are a nurse working with a large maxillofacial surgery group who attended a conference on integrative nursing. One presenter that stood out discussed the benefits of acupuncture/acupressure in managing gag reflex in patients undergoing dental procedures. Gagging is a common problem encountered during dental treatment, making therapeutic procedures distressing and often difficult or even impossible to perform. One of the surgeons asks if you learned something new at the conference and you discuss the results of the presentation.

The office currently only uses sedatives to facilitate sedation in patient undergoing procedures. You wonder if acupuncture/acupressure compared to sedatives has any benefit in the care of patients specifically pediatric patients undergoing procedures.

- **Population:** Patients receiving sedation for dental procedure
- **Intervention:** Use of acupuncture/acupressure
- **Comparison:** Use of sedatives
- **Outcome:** Decreased gag reflex
- **Time:** During dental procedures

PICOT Question: Does the use of acupuncture/acupressure by a nonanesthesiologist compared to administration of sedatives result in depression of gag reflex in children and adults undergoing dental treatment and improved experience?

Findings:

1. Ashley, P. F., Chaudhary, M., & LourençoMatharu, L. (2018). Sedation of children undergoing dental treatment. *Cochrane Database of Systematic Reviews*, *12*(12), CD003877. https://doi.org/10.1002/14651858.CD003877.pub5.

Included 50 studies with a total of 3,704 children up to age 16 years. Thirty-four different sedatives were used,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

often with inhalational nitrous oxide as well. Dosages, mode of administration and time of administration varied widely. Studies were grouped into placebocontrolled, dosage and headtohead comparisons. Metaanalysis of the available data for the primary outcome (behavior) was possible for studies investigating oral midazolam versus placebo only. There was moderatecertainty evidence that oral midazolam is an effective sedative agent for children undergoing dental treatment. There is a need for further welldesigned and wellreported clinical trials to evaluate other potential sedation agents.

2. Eachempati, P., Kumbargere Nagraj, S., Kiran Kumar Krishanappa, S., George, R. P., Soe, H. H. K., & Karanth, L. (2019). Management of gag reflex for patients undergoing dental treatment. *Cochrane Database of Systematic Reviews, 2019*(11), CD011116. https://doi.org/doi: 10.1002/14651858.CD011116.pub3

The interventions used to manage gagging include antinausea medicines, sedatives, local and general anesthetics, herbal remedies, behavior therapy, and cognitive behavior therapy, acupressure, acupuncture, laser, and prosthetic devices. This systematic review included four trials with 328 people (263 adults and 65 children who were age 4 years or older). Of the trials reviewed, one compared acupuncture and acupressure (with thumb, device, and sea band) at P6 (point located threefinger breadths below the wrist on the inner forearm in between the two tendons) to sham acupuncture and acupressure with and without sedation. One trial compared acupuncture at P6 point to sham acupuncture. P6 is an important acupuncture point in the Jueyin Pericardium Meridian of Hand. These trials reported both completion of dental procedure and reduction in gagging as their outcomes.

Strength of Evidence: Level I: systematic review

Recommendations: Conscious sedation or moderate sedation is the ability of the patient to independently maintain an open mouth and respond sensibly to verbal commands. In addition, the patient will retain adequate function of protective reflexes such as the gag reflex. There is a fine line between a sedated patient to an anaesthetized patient. The ideal sedative agent would reduce anxiety and improve behavior. Oral midazolam probably improves behavior of children during dental treatment. Acupuncture at P6 point (a point located in the inside of the wrist) when compared to acupressure to reduce gagging when undergoing dental procedures is appropriate. The same intervention with sedation did not show a difference. You discuss these findings with the maxillofacial surgery group and suggest offering integrative therapies for patients undergoing dental procedures.

Box 29-3 **Tips for Talking With Health Care Providers**

Patients can stay in better control and effectively manage their health when they share their use of complementary health practices. This information also ensures health care providers are better able to help patients make wise health care decisions (NCCIH, 2020e).

Encourage patients to:

- List the complementary health practices used to provide a full picture of what they do to manage their health when completing a patient history form.
- Tell their health care provider about any complementary health approaches used at every health care visit. Include over the counter and prescription medicines, and dietary and herbal supplements.
- Ask questions about any new complementary health practice they may be considering for use.
- Be proactive. Don't wait for their health care provider to ask about any complementary health practice they are using—start the conversation.

Source: Adapted from National Center for Complementary and Integrative Health (NCCIH). (2020, October 8). *4 tips: Start talking with your health care providers about complementary health approaches.* https://www.nccih.nih.gov/health/tips/tips-start-talking-with-your-health-care-providers-about-complementary-health-approaches

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the goal of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop expertise in implementing measures related to complementary and integrative health practices, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following while performing interventions related to CHAs and integrative health care and providing nursing care:

- Were you aware of any cultural and/or ethnic beliefs or practices that may have influenced the health practices and beliefs of patients and/or family members/caregivers related to CHA/IH? Were you aware of any stereotypes or prejudices that might have negatively influenced the clinical encounter? If so, how did you address these?
- Was the patient/family/caregiver participation in the process at an optimal level? How might you have better engaged the patient and family/caregivers? Did the patient sense that you are respectful, caring, and competent to obtain accurate and relevant data?

- What knowledge from your learning, personal experience, and intuition did you use to make decisions and develop your plan of care?
- Did your preparation and practice related to performing interventions related to CHA/IH result in your feeling confident in your ability to provide care? Did your competence and confidence inspire the patient's and family's/caregiver's trust?
- As you concluded your care, did the patient/family/caregivers know your name and know what to expect of you and your nursing? Did the patient sense that you are respectful, caring, and competent to provide care?

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to address their CHA/IH needs? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. You are caring for a culturally diverse population. How would you appropriately assess for and implement CHA into your nursing care, simultaneously demonstrating respect for your patients' beliefs and preferences while honoring your commitment to evidence-based nursing/medicine?

. The family of a woman dying of cancer approaches you with a brown paper bag of ground herbs and asks you to mix them with the patient's next tube feeding. They are very upset that she isn't healing and believe the herbs might help. How do you respond and what is the basis for your response? Talk with other students about what they would do and compare your responses.

. A nurse who practices TT tells you that she finds it very helpful for all sorts of patients. When you press her for details, you learn that she even practices this technique on patients without their consent while they are sleeping. Are you troubled by this? Is patient consent needed for CHA in the same way it is needed for allopathic treatments?

. A patient brings you a newspaper article discussing some potential alternative therapies. Part of the article states: "Thanks to a $374,000 taxpayer-funded grant, we now know that inhaling lemon and lavender scents doesn't do a lot for our ability to heal a wound. With $666,000 in federal research money, scientists examined whether distant prayer could heal AIDS. It could not. The National Center for Complementary and Integrative Health also helped pay scientists to study whether squirting brewed coffee into someone's intestines can help treat pancreatic cancer (a $406,000 grant) and whether massage makes people with advanced cancer feel better ($1.25 million). The coffee enemas did not help. The massage did." He asks you how he can know "what works?" How do you reply?

PRACTICING FOR NCLEX

. A patient recovering from a myocardial infarction tells the nurse: "My life feels out of control since I had the heart attack. I'd like to try yoga, but I don't think I'm strong enough to hold poses for long." What response by the nurse is most appropriate?

a. "Concentrate on relaxing and taking your blood pressure medicine regularly; don't worry about doing yoga."
b. "Yoga can lower stress. Seek a slow-paced, gentle class when you are cleared for activity."
c. "Ashtanga yoga is a gently paced yoga that can help with breathing and blood pressure."
d. "Yoga is contraindicated for patients who have had a heart attack."

. A nurse is providing education on CHAs to a group of patients in a rehabilitation facility. Which statement is appropriate for the nurse to include?

a. "CHAs are safe interventions used to supplement traditional care."
b. "Many patients use CHAs as outpatients but do not wish to continue as inpatients."
c. "Many nurses incorporate CHAs; could we try a relaxation exercise together?"
d. "Most CHAs are newer, and effectiveness has not been established.

. A nurse mentor is teaching a new nurse about the underlying beliefs of CHAs versus allopathic therapies. Which statements by the new nurse indicate that teaching was effective? Select all that apply.

a. "CHA proponents believe the mind, body, and spirit are integrated and together influence health and illness."
b. "CHA proponents believe that health is a balance of body systems: mental, social, and spiritual as well as physical."
c. "Allopathy proponents believe that the main cause of illness is an imbalance or disharmony in the body systems."
d. "Curing, according to CHA proponents, seeks to destroy the invading organism or repair the affected part."
e. "Allopathic proponents place emphasis on disease, and drugs, surgery, and radiation are key tools for curing."
f. "According to CHA proponents, health is the absence of disease."

. A nurse plans to include integrative care for a patient who has many functional limitations related to painful rheumatoid arthritis. Which nursing intervention best represents the use of integrative care?

a. The nurse administers naproxen and uses guided imagery to promote relaxation and promote pain relief.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

b. The nurse prepares the patient's health care provider–approved herbal tea and uses meditation to relax the patient prior to bed.
c. The nurse administers naproxen and performs prescribed range-of-motion exercises.
d. The nurse arranges for acupuncture for the patient and designs a menu high in omega-3 fatty acids.

. A nurse works in a practice with naturopathic health care providers. What nursing actions would this nurse perform? Select all that apply.
a. Treating the symptoms of the disease
b. Providing patient education
c. Focusing on treating individual body systems
d. Suggesting interventions to prevent illness
e. Incorporating the healing power of nature
f. Encouraging patients' responsibility for their own health

. A nurse cares for patients in a chiropractic office. What patient education would the nurse perform? Select all that apply.
a. Proper application of heat or ice
b. Explaining the purpose of electrical stimulation
c. Teaching relaxation techniques
d. Educating about a prescription medication
e. Teaching before an invasive procedure
f. Using safety with dietary supplements

. A nurse colleague with severe arthritis of the hip tells you they would like to incorporate use of medical marijuana into their pain relief regimen. What is most appropriate to share with your colleague?
a. Marijuana is a controlled substance.
b. Even where marijuana is legal, employees testing positive for THC may be disciplined.
c. This is an effective tool for many people for pain management.
d. The regulation of marijuana for recreation use is different than for employment.

. A nurse is guiding a group of patients in a meditation practice. Which teaching point is most appropriate to help the patients achieve a state of calmness, physical relaxation, and psychological balance?
a. Always lie down in a comfortable position during meditation.
b. Focus on multiple problems that they feel demands attention.
c. Allow distractions to come and go naturally without judging them.
d. Suppress distracting or wandering thoughts to maintain focus.

. A nurse working in an inpatient hospice facility incorporates aromatherapy into their practice. For which patient problem will ginger be most helpful?
a. Insomnia
b. Nausea
c. Dementia
d. Pain

. A nurse manager working in a hospital setting is researching the use of energy healing as an integrative care practice. Which patient would most likely benefit from this type of CHA?
a. One who is anxious about residual pain from cervical spinal surgery
b. One who is experiencing abdominal discomfort
c. One who is experiencing chronic pain from diabetes
d. One who has frequent cluster headaches

. A nurse in the pain management clinic is explaining complementary health approaches to a patient with severe back pain who is interested in holistic health. What approaches could the nurse include in the discussion? Select all that apply.
a. Acupressure or acupuncture
b. Qi gong or tai chi
c. Minimally invasive surgery
d. Gentle yoga
e. Aromatherapy

. A patient with chronic pain tells the nurse they are very tired and sleeping fitfully. What actions promoting sleep

hygiene will the nurse suggest?

a. Sleep with a night light on.
b. Play soft, pleasing music.
c. Perform a relaxation exercise.
d. Establish a regular sleep–wake schedule.
e. Minimize noise.

ANSWERS WITH RATIONALES

. **b.** Kripalu, or "gentle yoga," focuses on relaxation and coming into balance. Ashtanga focuses on synchronizing breath with a fast-paced series of postures. The nurse should not discourage the use of yoga in patients who are healthy enough to participate. Yoga is not contraindicated in patients with controlled high blood pressure. Post-MI patients should resume activity with guidance from the health care provider.

. **c.** Many nurses are expanding their clinical practice by incorporating CHAs. Although many CHAs seem safe, some therapies have led to harmful or lethal outcomes. Patients should seek guidance from the provider. Many patients use these types of therapies as outpatients and choose to continue them as inpatients. Most complementary and alternative therapies predate modern medicine; it was not until recently that nursing and medical schools began to teach about their use.

. **a, b, e.** With CHAs, mind, body, and spirit are integrated and together influence health and illness; illness is a manifestation of imbalance or disharmony. Allopathic beliefs include: The main causes of illness are considered to be pathogens (bacteria or viruses) or biochemical imbalances, curing seeks to destroy the invading organism or repair the affected part, and emphasis is on disease and high technology. Drugs, surgery, and radiation are among the key tools for dealing with medical problems. According to allopathic beliefs, health is the absence of disease.

. **a.** Patient participation in guided imagery (a CHA) with the administration of pain medications (allopathy) is an example of integrative care. Integrative care uses some combination of allopathic medicine and CHAs.

. **b, d, e, f.** Naturopathic medicine is a system of medicine and a way of life. Emphasis is on patient responsibility, patient education, health maintenance, and disease prevention. Its principles include minimizing harmful side effects and avoiding suppression of symptoms, educating patients and encouraging them to take responsibility for their own health, treating the whole person, preventing illness, believing in the healing power of nature, and treating the cause of a disease or condition rather than its symptoms.

. **a, b, c, f.** Chiropractors may combine the use of spinal adjustments and other manual therapies with several approaches including heat and ice, electrical stimulation, relaxation techniques, rehabilitative and general exercise, counseling about weight and diet, and using dietary supplements. Chiropractors do not prescribe medication or perform invasive procedures.

. **b.** THC is the psychoactive substance found in marijuana. Marijuana used for health problems or recreational use may be legal based on state law. However, for persons employed in safety-sensitive positions, such as nursing, the presence of THC or its constituents may pose a threat to health and safety. A positive test for THC may result in disciplinary action by an employer.

. **c.** Meditators are encouraged to let distractions come and go naturally without judging them. Assuming a comfortable posture lying down, sitting, standing, or walking is appropriate, as is focusing attention on a mantra, object, or breathing. The individual should not suppress distracting or wandering thoughts; instead, they should gently bring attention back to focus.

. **b.** Commonly used essential oils in a health care setting are ginger or peppermint for nausea and lavender or chamomile for insomnia.

. **a.** Energy healing is focused on pain that lingers after an injury heals as well as pain complicated by trauma, anxiety, or depression. Nutritional and herbal remedies treat all chronic pain, but especially abdominal discomfort, headaches, and inflammatory conditions, such as rheumatoid arthritis.

. **a, b, d, e.** Holistic nursing is based on the philosophy of holism, which incorporates the mind, body, and emotions. Further, the interrelationships of the bio-psycho-social-spiritual dimensions of the person are greater than and not separate from their parts. Conventional scientific models focus on treatment of health conditions, individual organs, or organ systems rather than the whole dynamic being as part of their environment. Surgical procedures do not address body, mind, and emotions.

. **b, c, d, e, f.** Creating an optimal sleep environment for deep, restorative rest includes establishing a regular sleep–wake schedule and minimizing light and noise. Music can promote relaxation and increase sleep quality, as can relaxation exercises.

Medications

Regina Sauder

Regina, a 73-year-old woman with a history of lymphoma, has presented to the emergency department with pain, swelling, and erythema (redness) of her left calf. She has been diagnosed with a left leg deep vein thrombosis (DVT). She is receiving intravenous heparin and oral warfarin. When she is discharged, she will need to have weekly blood testing to ensure therapeutic levels of the warfarin.

Mildred Campbell

Mildred, a 65-year-old woman with a history of arthritis and hypertension (high blood pressure), comes to the clinic for evaluation of her painful joints. She states, “I just saw this new medicine advertised on television that is supposed to be really helpful in relieving joint pain. What do you think? Is it something I should try?”

François Baptiste

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

François is an older adult with a wound infection requiring intravenous antibiotic therapy. He is scheduled to receive his next dose at 1000. The medication delivered by the pharmacy is labeled with the correct drug and dose, but with a different patient's name.

Lippincott DocuCare Additional patient scenarios available in *Lippincott DocuCare*.

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Discuss drug legislation in the United States.
. Describe basic principles of pharmacology, including drug nomenclature and types of drug preparations.
. Develop an understanding of basic principles of pharmacology, including mechanisms of drug action, adverse drug reactions, and factors affecting drug action.
. Discuss principles of medication administration, including an understanding of medication orders, dosage calculations, and medication safety measures.
. Obtain patient information necessary to establish a medication history.
. Describe principles used to prepare and administer medications safely by the oral, parenteral, topical, and inhalation routes.
. Use a systematic process for medication administration such as the Nursing Process to safely administer medications.
. Develop teaching plans to meet patient needs specific to medication administration.

toxic effects
trade name
trough level
vial
Z-track technique

A drug or medication is any substance that modifies body functions when taken into the body. The study of drugs and their effect on the body's functioning is called **pharmacology**. A pharmacist is a person licensed to prepare and dispense drugs. Physicians, dentists, psychiatrists, podiatrists, physician assistants, and advanced practice nurses have prescriptive authority. Prescriptive authority for advanced practice nurses (clinical nurse specialists, nurse practitioners, certified nurse anesthetists, nurse midwives) and physician assistants varies in the degree of independence and the medications that may be prescribed from state to state. Nurses must be familiar with the laws relative to prescriptive authority in their state of practice. The prescriber conveys medication plans to others by an order called a *prescription*. In a hospital or other health care facility, after the pharmacist prepares the medication, the nurse administers the medication to the patient. This chain provides a system of checks-and-balances for medication administration. If an error is made when the order is written, the pharmacist or nurse administering the medication has the opportunity to note the discrepancy. If an error occurs when the pharmacy dispenses the medication, the administering nurse has the opportunity to note this discrepancy. See the accompanying Reflective Practice box (on pages 914–915) for an example.

Medication administration is a core nursing function that involves skillful technique and consideration of safety principles that consider the patient's developmental state, individual characteristics, and health status. The nurse administering medications needs to have knowledge of drugs, including drug names, preparations, classifications, adverse effects, and physiologic factors that affect drug action. Information about specific drugs is available in pharmacology texts and drug reference books. Computer programs and electronic databases are available for up-to-date medication information. Nurses must have sufficient knowledge about the drugs being administered to safely care for their patients. The Joint Commission has made several recommendations regarding safe practice when administering medications. Up-to-date information about these recommendations can be found at https://www.jointcommission.org/standards/national-patient-safety-goals/.

The nursing process can be applied to medication administration. Assessment includes a comprehensive medication history, awareness of the patient's allergies, and patient assessment, as well as ongoing assessments of the patient's

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

response during and after medication administration. Diagnoses are developed and problem identification stems from the assessment data. Patient-centered outcomes are evaluated after implementation of the plan of care and are tailored to the patient's needs.

PRINCIPLES OF PHARMACOLOGY

An overview of basic pharmacology includes drug nomenclature, types of drug preparations, drug classification, drug indication, mechanisms of drug action, adverse drug reactions, side effects, and factors affecting drug action, as well as drug blood level monitoring and pertinent U.S. drug legislation.

Drug Nomenclature

Drugs have several names, and are most commonly referred to by their generic and trade names. The **generic name**, which identifies the drug's active ingredient, is the name assigned by the manufacturer that first develops the drug. Often, the generic name is derived from the chemical name, which is a precise description of the drug's chemical composition that identifies the drug's atomic and molecular structure using exact chemical language and terminology. The generic name is not owned by any drug company and is universally accepted. The official name (also known as a *monograph*) is the name by which the drug is identified in publications such as the United States Pharmacopeia (USP) and National Formulary (NF; USP-NF, 2020). The official name is typically the generic name. The **trade name**, also referred to as the *brand name*, is selected by the pharmaceutical company that sells the drug and is protected by trademark. A drug can have several trade names when produced by different manufacturers.

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO ETHICAL AND LEGAL SKILLS

During my clinical rotation for complex care a few weeks ago, I met François Baptiste, an older adult with a wound infection requiring intravenous antibiotic therapy. He was due for a certain IV antibiotic to be hung at 1000. When I checked his drawer at 0800 and 0900, the antibiotic was not there. However, the nurse I was working with told me not to call pharmacy about it yet since the pharmacy staff often comes and replaces the drawers in the medication carts before 1000 anyway. Sure enough, a pharmacy representative came up that hour and changed the medication drawers. At 1000, I went to look in my patient's drawer. What I found confused me a great deal! Yes, the bag of medication was in there. Yes, it was the right drug and the right dose. However, it was the wrong patient! The label on the bag in my patient's drawer had another patient's name on it. I looked up information on that other patient, and it turned out he was also a patient on the unit. This patient was also receiving the same drug, at the same dose, but at a different time. I wondered if I should hang this bag for my patient because he was due for it, even though it had someone else's name and medical record number on the label. It was, after all, the same drug and the same dose.

Thinking Outside the Box: Possible Courses of Action

- Change the patient's name on the label and hang the bag.
- Call pharmacy to ask about the mix-up. If the bag really did contain the same medication at the same dose, then change the patient's name on the label and hang it for my patient.
- Check the other patient's medication administration record (MAR) to confirm that he is, indeed, receiving the same drug at the same dose as my patient, and if so, use this bag for my patient (since it is in my patient's drawer and my patient is due for it).
- Ask my nurse and/or preceptor what to do. Is it okay, safe, and legal to use this bag if someone else's name is on the label? If they say yes, check with the nurse caring for the patient whose name is on the label to make sure they don't not need the medication right now.
- Send the bag back to pharmacy, requesting they send up a new one with an accurate label.
- Call pharmacy, ask them to send up a new bag with an accurate label, and tell them I am giving the other bag to the other patient's nurse.

Evaluating a Good Outcome: How Do I Define Success?

- The right patient receives the right drug, at the right dose, at the right time, via the right route, with the right documentation, understanding the right rationale.
- The patient feels comfortable and safe with the drug being administered to him.
- The needs of my patient and those of the patient whose name was on the bag are assessed and met. Both patients have the medication available to them when they are due to receive it.

- My education and my license are not put at risk by an avoidable medication error.
- My legal skills are sharpened by thinking and working through the situation.

Personal Learning: Here's to the Future!

Ultimately, I addressed the situation step-by-step to make sure all the bases were covered. First, I checked the other patient's drawer to see if he had a bag of this IV antibiotic. He did not, which led me to believe that either his bag was placed in my drawer by accident, or his bag had not been made yet. Then I checked my patient's MAR and that of the other patient. Indeed, both were scheduled to receive the same drug, at the same dose, via the same route. However, my patient was due for it at 1000, the other patient was due for it at 1400. Next, I brought the medication bag, the MARs, and my other paperwork to my clinical instructor and to the nurses caring for my patient and the other patient. They all agreed that the bag that was in my drawer was the right drug at the right dose, even though it had the wrong name on the label. However, it is not the nurse's responsibility or legal right to dispense medication. For this reason, the bag of medication needed to be returned to the pharmacy because it was labeled with the wrong name. The pharmacist must relabel the medication, thus preparing and dispensing a correctly labeled dose for each patient. I called the pharmacy, explained what I had found, and told them I would be returning the dose that had been delivered to my patient. I requested a correct dose for 1000 for my patient. The pharmacy delivered a new bag of medication, correctly labeled, in time for the patient's 1000 dose. After checking everything again, I administered the medication to my patient. My patient did not have an adverse reaction, the other patient got his medication when it was due, and no mistakes were made by any of the nurses. The only mistake that was made was by pharmacy—they put the wrong label on the bag and then put the bag in the drawer.

I learned that checking and double-checking medication labels is extremely important. After a while, we all have a tendency to get into the habit of glancing at things when we are in a hurry, especially when it involves labels we look at all the time, feeling confident that we would recognize a problem. This is not the first time I could have missed a change on the label—there have been several times when I did not think to check every single thing on a label. That's because after giving it so many times, I felt it had become routine. But every time I am tempted not to double-check a label, I am reminded of this situation. As a result, I triple-check things because those are the times when I may not be paying as close attention as I need to be. Because I do not have my license yet, I am still learning all the laws and regulations surrounding medication administration. However, as a student nurse, I am careful to avoid any mistakes that could place me in jeopardy legally for areas of which I *am* aware. In addition, I am always careful to protect my education and my future as a nurse by not doing things about which I am uncertain. I always ask my preceptor or my nurse for help or advice when I need it. While my legal skills probably need some work, they are certainly not terrible, and my skills and I are moving in the right direction.

Tracey Sara Miller, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? Do you agree with the criteria to evaluate a successful outcome? Did the nursing student validate the rationale for the outcome? What *knowledge, skills, and attitudes* do you need to develop to continuously improve the quality and safety of care for patients like Mr. Baptiste?

Patient-Centered Care: Would it have been appropriate for the nursing student to change the name on the label? Why or why not? How did the nursing student's actions adhere to ethical and legal principles? Did the nursing student act as an advocate for Mr. Baptiste?

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to improve to ensure that you communicate appropriately in situations like this? What communication skills do you need to improve to ensure that you could address this issue as a member of the patient-care team? How can you ensure that this event is used to prevent similar issues in the future to improve the quality of care?

Safety/Evidence-Based Practice: How can you communicate observations or concerns related to hazards and errors to patients, families, and the health care team? What is your role in preventing errors? What legal principles did the nursing student adhere to with the described actions? Suppose the nursing student had given the medication without double-checking all of the information. What legal principles might have been violated? What evidence in nursing literature provides guidance for decision making regarding care of this patient? What does this tell you about yourself and about the adequacy of your skills

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

for professional practice?

Informatics: Can you identify the essential information that must be available in Mr. Baptiste's electronic health record (EHR) to support safe patient care and coordination of care? What information should be documented in the EHR regarding the student's assessment and interventions? Can you think of other ways to respond to or approach the situation?

Nurses should be familiar with both generic and trade names. For example, acetaminophen (generic name) has trade names such as Tylenol, Tempra, and Liquiprin. The generic name is universal and is not likely to change; however, the trade name will change depending on the specific company and manufacturer. Health care entities vary in their use of generic-only or both the generic and trade names. Electronic medication administration records (eMARs) typically default to the generic names, but may include both the generic and trade names. In conversations with interprofessional/intraprofessional teams and with patients, the trade name is often used because it is frequently easier than the generic name to articulate or spell. In drug literature and in clinical practice, trade names are capitalized and generic names are presented in lowercase unless they are in a list or used at the beginning of a sentence (Frandsen & Pennington, 2021; Karch, 2020). Developing a working knowledge of the generic and trade names of drugs is an important part of the nurse's responsibilities when transcribing orders and administering medication therapies.

Types of Drug Preparations

Drugs are available in many forms, or preparations. The form in which the drug is prepared may determine the route of administration. Drug preparations are available for enteral (oral), topical, and parenteral (injection, infusion, implantation) administration. Some drugs may be prepared in only one form to be administered by a certain route. Others may be supplied in several preparations, allowing them to be given through various routes. One type of preparation may be desirable in a given situation. For example, a liquid preparation of a medication would be indicated for a young child who cannot swallow solid preparations, such as tablets. A suppository may be indicated to deliver a medication for a patient who cannot take anything by mouth. Table 30-1 (on page 916) describes drug preparations commonly used by nurses.

Drug Classifications

Drug classifications, or drug classes, refer to groups of drugs that share similar characteristics. Drugs are classified in two primary ways: pharmaceutical class and therapeutic class. The pharmaceutical class refers to the mechanism of action (MOA), physiologic effect (PE), and chemical structure (CS) of the drug (U.S. Food and Drug Administration [FDA], 2018a). The therapeutic class refers to the clinical indication for the drug or therapeutic action (e.g., analgesic, antibiotic, or antihypertensive). General knowledge related to the class of drug can assist with understanding specific drugs in that same class.

Drug Indications

Pharmacotherapeutics is a subtopic of pharmacology that considers the "therapeutic uses and effects of drugs" (Merriam-Webster, n.d.). It addresses *why* we administer a specific drug, which is more commonly known as the *clinical indication(s)*. Understanding the desired outcome of administering a drug is an important part of nursing responsibilities related to medication administration. Nurses are legally responsible for understanding the pharmacotherapeutics of all drugs they administer. This knowledge is required for the practicing nurse to assess the appropriateness of the medication, as well as provide appropriate and accurate patient education (Frandsen & Pennington, 2021; Karch, 2020).

Table 30-1 Common Types of Drug Preparations

PREPARATION	DESCRIPTION
Capsule	Powder or gel form of an active drug enclosed in a gelatinous container; may also be called liquigel
Elixir	Medication in a clear liquid containing water, alcohol, sweeteners, and flavor
Enteric coated	A tablet or pill coated to prevent stomach irritation
Extended release (ER)	Preparation of a medication that allows for slow and continuous release over a predetermined period; may also be referred to as CR or CRT (controlled release), SR (sustained or slow release), SA (sustained action), LA (long acting), or TR (timed release)

Liniment	Medication mixed with alcohol, oil, or soap that is rubbed on the skin
Lotion	Drug particles in a solution for topical use
Lozenge	Small oval, round, or oblong preparation containing a drug in a flavored or sweetened base that dissolves in the mouth and releases the medication; also called *troche*
Ointment	Semisolid preparation containing a drug to be applied externally; also called an *unction*
Pill	Mixture of a powdered drug with a cohesive material; may be round or oval
Powder	Single or mixture of finely ground drugs
Solution	A drug dissolved in another substance (e.g., in an aqueous solution)
Suppository	An easily melted medication preparation in a firm base such as gelatin that is inserted into the body (rectum, vagina, urethra)
Suspension	Finely divided, undissolved particles in a liquid medium; should be shaken before use
Syrup	Medication combined in a water and sugar solution
Tablet	Small, solid dose of medication, compressed or molded; may be any color, size, or shape (e.g., caplets are elongated/oval in shape and are often coated); *enteric-coated tablets* are coated with a substance that is insoluble in gastric acids to reduce gastric irritation by the drug
Transdermal patch	Unit dose of medication applied directly to skin for diffusion through skin and absorption into the bloodstream

Mechanisms of Drug Action

Pharmacokinetics

Pharmacokinetics is the effect the body has on a drug once the drug enters the body. It is the movement of drug molecules in the body in relation to the drug's absorption, distribution, metabolism, and excretion.

ABSORPTION

Absorption is the process by which a drug is transferred from its site of entry into the body to the bloodstream. Absorption of a drug is influenced by the following factors.

Route of Administration

The rate of absorption depends on the route of administration. Drugs given orally usually take the longest to be absorbed, with liquids that do not need to be dissolved having a faster absorption rate than capsules or tablets. Drugs injected intramuscularly or subcutaneously are usually absorbed more rapidly than oral medications. Drugs administered intravenously are placed directly into the bloodstream, thus technically are not absorbed and take effect quickly. Drugs administered through intact skin, unless formulated specifically for systemic absorption (transdermal patches), tend to have primarily local effects. However, drugs administered via a mucous membrane (oral mucosa, eye, nose, vagina, or rectum) are absorbed both locally and systemically, which means the drug acts right at the site of administration, but also passes directly into the bloodstream. The portion of a drug that reaches the systemic circulation and can act on the cells is called the drug's **bioavailability** (Frandsen & Pennington, 2021).

Lipid Solubility

Cell membranes have a fatty acid layer. A drug that is more lipid soluble can be absorbed more readily and pass more easily through the cell membrane.

pH

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Acidic drugs are well absorbed in the stomach. Drugs that are alkalotic remain ionized or insoluble in an acidic environment. These drugs are not absorbed before reaching the small intestine. The concept of acid–base balance is further discussed in Chapter 42.

Blood Flow

Absorption is increased with increased blood flow. Patients with impaired circulatory function absorb drugs less rapidly than patients with normal circulatory function.

Local Conditions at the Site of Administration

The more extensive the absorbing surface, the greater the absorption of the drug and the more rapid the effect. For example, a patient with burns would have poor absorption from an intramuscular injection because of the damage to the blood supply typically present in muscle. Food, especially fatty food that slows gastric emptying, can slow the rate of absorption of some drugs; but food may enhance the rate of absorption of poorly soluble drugs. Since most of the absorption in the gastrointestinal tract takes place in the small intestine, the length of time a drug is present in the intestinal tract (diarrhea or vomiting) affects absorption and drug bioavailability. Drug absorption can be manipulated with sustained-release preparations or enteric-coated preparations, which are primarily absorbed in the small intestine (Le, 2019). Enteric-coated preparations are resistant to the digestive action of the stomach.

Drug Dosage

When determining a drug dosage, providers consider absorption, distribution, metabolism, and elimination. The amount of a drug administered directly impacts its bioavailability. For example, a loading dose, or a larger than normal dose, is usually given when a patient is in acute distress and the maximum therapeutic effect is desired as quickly as possible. Serum drug levels (which require a blood-draw and laboratory analysis) help determine dosage by reflecting absorption, bioavailability, and drug half-life, as well as metabolic and excretory rates. Serum drug levels ultimately indicate the onset, peak, and duration of action (Frandsen & Pennington, 2021). These laboratory values become especially important when the margin of error between a therapeutic level and toxic level is narrow. If drug toxicity occurs, it can be detected quickly and treated in the controlled hospital environment. A maintenance dose is a lower dosage that becomes the usual or daily dosage. Patients who receive digoxin or phenobarbital, for example, may receive loading doses when therapy is initiated and then transition to a maintenance dose. The goal of drug dosing is to give a dose that achieves the desired therapeutic effect of the drug (pharmacotherapeutics) without causing other undesirable or adverse reactions (discussed later in this chapter).

DISTRIBUTION

Distribution occurs after a drug has been injected or absorbed into the bloodstream—the drug molecules are transported throughout the body to where they take action. Metabolism and excretion occur after distribution. Distribution depends on: (1) the adequacy of blood circulation; (2) protein binding, which affects the drug's ability to leave the bloodstream or storage areas (such as muscle, fat, or other tissues) and enter the cells; and (3) the selectively permeable blood–brain barrier that protects the central nervous system (CNS) with its capillary wall, but can also limit the passage of drugs intended to act on the CNS (Frandsen & Pennington, 2021). In the case of pregnancy and lactation, some drugs readily cross the placenta and/or enter breast milk. These factors must be considered when planning and implementing drug therapies. Any concern about the safe use of a medication during pregnancy can be identified in a pharmacology text, through consultation with a pharmacist, or from trusted computer programs and electronic databases.

METABOLISM

Metabolism, or biotransformation, is the change of an active drug from its original form to an inactivated or new form (Frandsen & Pennington, 2021; Karch, 2020). The liver is the primary site for drug metabolism. Various processes and enzymes are involved in metabolism. Most drugs are inactivated by the liver and transformed to inactive substances for excretion (discussed in the next section). Physiologic changes associated with aging, the presence of liver disease, or other factors that impair the functioning of the liver decrease its ability to metabolize drugs. Other tissues, such as those of the gastrointestinal tract, lungs, and kidneys, also have a role in drug metabolism (Frandsen & Pennington, 2021; Karch, 2020).

Drugs given orally move from the intestinal lumen to the liver by way of the portal vein. Some drugs are extensively metabolized in the liver and do not make it to the systemic circulation. This reduction in bioavailability is referred to as the *first-pass effect* or presystemic metabolism (Frandsen & Pennington, 2021; Karch, 2020). Drugs with extensive or variable first-pass effects, such as nitroglycerin, are not given orally because most of the drug would be destroyed by the liver, with little or no drug left to work in the body. This is why nitroglycerin is only given via sublingual, transdermal, or intravenous routes (McCuistion et al., 2021). Some drugs are metabolized by the liver to an inactive form, reducing the amount of active drug left in the body. Other drugs may be metabolized to an active drug metabolite (another form), and may be more active than the original drug. Pharmacology texts provide more detailed explanations of the metabolism of drugs.

EXCRETION

After the drug is broken down to an inactive form, excretion of the drug occurs. **Excretion** is the process of removing a drug, or its metabolites (products of metabolism), from the body. The kidneys excrete most drugs through urine. The lungs are the primary route for the excretion of gaseous substances, such as inhalation anesthetics. Some drugs or their metabolites are excreted through bile—either directly through feces or returned to the liver and then eventually excreted by the kidney. The skin has minimal excretory function (Frandsen & Pennington, 2021). Some medications may be contraindicated, or dosages may need to be adjusted, if renal excretion is impaired. Changes associated with aging, disease, or the presence of other factors that impair the functioning of the kidneys can decrease their ability to excrete drugs. Manufacturers are required by law to include specific information regarding implications for specific populations, including geriatric or pregnant patients, on the package inserts of prescription drugs and biologic products (FDA, 2020). Of particular concern are details concerning the excretion of these drugs in older adults whose renal function has declined.

Pharmacodynamics

Drugs act at the cellular level to achieve the desired effects. The process by which drugs act on target cells, resulting in alterations in cellular reactions and functions, is called **pharmacodynamics**. Pharmacodynamics represents what a drug does to the body (Farinde, 2019). Drugs turn on, turn off, promote, or block responses that are part of the body's processes. One mechanism of drug action is a drug–receptor interaction, in which the drug interacts with one or more cellular structures to alter cell function. These specialized structures are called receptor sites. The drug fits the receptor just like a key fits a lock. Drugs may also combine with other molecules in the body to achieve their effect. For example, a drug may combine with an enzyme to achieve the desired effect, which is referred to as a drug–enzyme interaction. Other drugs achieve their effect by acting on the permeability of the cell membrane, or altering the cellular environment via neurohormones that regulate key physiologic processes (Frandsen & Pennington, 2021).

Adverse Drug Reactions

Although a therapeutic effect is the desired outcome in medication administration, sometimes secondary undesirable effects occur. Harmful effects that lead to injury are known as adverse effects, adverse drug events (ADEs), and **adverse drug reactions (ADRs**; Frandsen & Pennington, 2021; Karch, 2020; Marsh, 2018).

Some unintended, secondary effects are mild, predictable, and may be tolerated as part of the therapy. These are often referred to as *side effects*. For example, morphine, an opioid agonist, is used to treat moderate to severe and chronic pain. A known side effect of morphine is constipation. However, the benefit of pain relief usually outweighs the side effect of constipation, so that side effect is often accepted and managed with stool softeners and laxatives. On the other hand, adverse reactions can be severe and may require discontinuation of the drug, depending on whether the benefit of the drug outweighs the harm from the adverse effect. For example, should the morphine cause a sudden drop in blood pressure, this may be considered an ADR and require intervention and discontinuation of the morphine.

Another example of an ADR is the development of an iatrogenic disorder caused unintentionally by drug therapy. Neutropenia caused by chemotherapy is an example of an ADR. Other types of ADRs to be discussed include allergic effects, drug tolerance, toxic effects, idiosyncratic effects, and drug interactions.

It is important for nurses and other health care professionals to monitor for ADRs. Serious ADRs, considered *adverse events* or sentinel events (discussed in Chapter 28), must be documented according to facility policy and should be reported to a national database, such as MedWatch. MedWatch is a safety information and voluntary adverse events reporting program, sponsored by the U.S. Food and Drug Administration (FDA, 2020). This program provides nationwide tracking of all serious ADRs, along with up-to-date information about medication errors and potential or actual medical-product problems and errors. According to FDA (2019) criteria, a serious ADE is defined as an action that is life threatening, requires intervention to prevent death or permanent impairment, and/or leads to death, hospitalization, disability, or congenital anomaly. Reporting of serious adverse effects is necessary for corrective action to take place to protect patients. This information is used to revise drug labels, add warnings for health care providers, create patient medication guides, or withdraw a drug from the market (FDA, 2019). One example of how this information is used is the addition of a Boxed Warning (formerly known as Black Box Warnings). These boxed warnings are placed on the label of certain prescription drugs (such as specific antidepressant and cancer-treatment drugs), to indicate the risk for serious ADRs and provide safety information (Delong & Preuss, 2020; Frandsen & Pennington, 2021). Additional information regarding reporting adverse events is discussed at the end of the chapter, in the section on Preventing and Responding to Medication Errors.

Unfolding Patient Stories: Mona Hernandez • Part 2

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Remember **Mona Hernandez** from Chapter 18, the 72-year-old female admitted with pneumonia. She has a history of hypertension controlled with hydrochlorothiazide 25 mg daily, continues to smoke a half pack of cigarettes per day, and is 20 lb overweight. The provider has ordered moxifloxacin 400 mg IV as a secondary line infusion (piggyback) daily to treat the pneumonia. What factors affecting drug action and potential adverse effects should the nurse consider before administering the antibiotic to Mona?

Care for Mona and other patients in a realistic virtual environment: **vSim** *for Nursing* (thepoint.lww.com/vSimFunds). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

Allergic Effect

An **allergic effect** is an immune system response that occurs when the body interprets the administered drug as a foreign substance and forms antibodies against the drug. A drug allergy manifests differently depending on the drug, the allergy, and the patient. Clinical manifestations of allergic reactions range from mild to severe. The reaction can occur immediately after the patient receives the medication or be delayed for hours to days. Symptoms may become more severe each time the drug is introduced into the body. Some of the signs and symptoms of a drug allergy are rash, urticaria, fever, diarrhea, nausea, and vomiting. The most serious allergic effect is called an **anaphylactic reaction** (anaphylaxis). **Anaphylaxis** is life threatening and results in respiratory distress, sudden severe bronchospasm, and cardiovascular collapse. This reaction is treated with vasopressors, bronchodilators, corticosteroids, oxygen therapy, intravenous fluids, and antihistamines.

Drug Tolerance

Drug tolerance occurs when the body becomes accustomed to the effects of a particular drug over a period of time. Larger doses of the drug must be taken to produce the desired effect. For example, patients using morphine for an extended period of time become tolerant to the drug's therapeutic effects and eventually need higher and higher doses to control their pain.

Toxic Effect

Toxic effects (toxicities) are specific groups of symptoms related to drug therapy that carry risk for permanent damage or death (Frandsen & Pennington, 2021). The organ or system affected by the toxicity is used to name the toxicity, such as with nephrotoxicity, or damage to the kidney. Toxicities can occur from a cumulative effect. A cumulative effect occurs when the body cannot metabolize one dose of a drug before another dose is administered. A mismatch between absorption and excretion means that each new dose increases the total quantity in the body. Older adults are especially at risk for experiencing a cumulative effect. This is related to altered drug metabolism and elimination due to impaired hepatic metabolism and renal clearance related to normal changes in these systems associated with aging. Researchers are working to quantify this risk and develop risk prediction models to improve early detection and prevent progressive organ damage in this vulnerable population (Tecklenborg et al., 2020).

Idiosyncratic Effect

An **idiosyncratic effect** (sometimes called *paradoxical effect*) is any unusual or peculiar response to a drug that may manifest itself by overresponse, underresponse, or even the opposite of the expected response. Idiosyncratic effects are related to a patient's unique response to a drug and are thought to be the result of genetic enzyme deficiencies that lead to an abnormal mechanism of drug breakdown. This term may become obsolete as ADR reporting continues and the specific mechanisms of ADRs are discovered (Marsh, 2018). Older adults often have unpredictable or erratic responses to medications.

Drug Interactions

Drug interactions occur when one drug is affected in some way by another drug, a food, or another substance that is taken at the same time. There are times when known drug interactions may be advantageous. For example, one medication may be given to offset or counteract another medication's side effects. Some medications are given together when their actions are synergistic or when one drug potentiates (increases) the therapeutic effects of another drug. Other drug interactions are not beneficial, especially when the drug interaction decreases the therapeutic effect and/or increases the adverse effects. In a drug–drug interaction, the combined effect of two or more drugs acting simultaneously can produce several effects (Frandsen & Pennington, 2021):

- Additive effect—drugs with similar pharmacologic actions; results in an increase in the overall effect
- Synergistic effect—drugs with different sites or MOA; results in greater effects when taken together (one drug potentiates the other)
- Antagonistic effect—combined drugs alter the overall sum effect or negate each other; results in an effect less than that of each drug alone
- Interference—one drug interferes with the metabolism of another; leads to the buildup of a medication (that cannot be metabolized) and can result in toxicity or an ADR
- Displacement—one drug binds to protein-binding sites and forces another drug to be displaced; results in the released

drug becoming pharmacologically active and can lead to an increase in the effect of the unbound drug

For example, ingesting alcohol and barbiturates together creates an unbeneficial **synergistic effect** with the potential for significantly increased CNS depression. It is important to be knowledgeable about and watch for drug interactions and the effects of drug therapy.

Think back to **Mildred Campbell**, the 65-year-old woman with arthritis and hypertension (high blood pressure) asking about a recently advertised medication for joint pain relief. The nurse should assess the patient's medication history to determine her current medication regimen and keep in mind that many older adults see more than one health care provider. The nurse must consider possible polypharmacy (taking of more than two medications at a time) and potential risks for drug interactions, even before discussing whether the advertised medication would be appropriate.

Dietary supplements, herbs, and other *natural* remedies are another potential problem area for drug interactions. Many patients do not consider dietary supplements, herbs, and natural remedies to be medications because they can purchase these items at a store selling nutritional products. However, many of these products have recognized pharmacologic effects, unexpected allergic reactions, and problematic drug–supplement interactions (Dudek, 2017; National Center for Complementary and Integrative Health [NCCIH], 2022). When asking patients if they are taking any medications, specifically ask if they are taking any herbal or natural supplements. Health care providers need to identify viable resources (Gregory et al., 2016) and be aware of the intended benefits, possible adverse effects, potential drug interactions, and perioperative implications related to these types of supplements. Further information related to dietary supplements, and natural and herbal products can be found at the FDA's website (https://www.fda.gov/food/dietary-Need to review supplements) and the NCCIH website (https://nccih.nih.gov).

Factors Affecting Drug Action

Certain variables can influence the action or effect of a medication. These variables include developmental considerations, patient's body weight, patient's biologic sex, genetic and cultural factors, psychological factors, pathology, environment, and timing of medication administration. In addition, social determinants of health play a role when considering availability of resources, access to education and health care, community resources, social support, health literacy, and access to emerging technologies.

Developmental Considerations

During pregnancy, many drugs are contraindicated because of their possible adverse effects on the fetus. Certain drugs, referred to as **teratogenic**, are known to have the potential to cause developmental defects in the embryo or fetus and are contraindicated. Examples of teratogenic drugs include cocaine, alcohol, neurologic medications (e.g., phenytoin and valproate), antimicrobials (e.g., tetracyclines and fluoroquinolones), anticoagulants (e.g., coumadin), antithyroid medications, and the hormonal medication, diethylstilbestrol (Arfman et al., 2020; Kobaly & Mandel, 2019; Tsamantioti & Hashmi, 2020). In 2015, the FDA (2020) replaced the drug classification categories (A, B, C, D, and X) with a new labeling system, the Pregnancy and Lactation Labeling Rule (PLLR), that addresses pregnancy, lactation, and females and males with reproductive potential. The timing (trimester, weeks) of administration during pregnancy, the dose of the medication, and a risk–benefit analysis inform decisions made by the pregnant person and their health care provider. Some drugs cross into breast milk, putting breastfed infants at risk for adverse effects from drugs in the breast feeding person's circulation. Small body size, reduced weight, and reduced body water also alter distribution, as do decreases in cardiac output and organ perfusion. Therefore, a child's medication dose is smaller than an adult's dose. Infants are especially sensitive to medications because of the immaturity of their organs and immaturity of the blood–brain barrier. Older people are sensitive to medications because their bodies have experienced physiologic changes associated with the aging process, including decreased gastric motility, muscle mass, acid production, and blood flow, which affect drug absorption. They may also be more susceptible to certain adverse effects. Liver function declines with advancing age,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and changes occur in the hepatic enzymes involved in drug metabolism. Blood flow to the liver decreases secondary to a decrease in cardiac output. Drugs are excreted more slowly from the body as a result of changes in kidney function. Receptor sensitivity is altered in older people, and their sensitivity to certain drugs increases. The physiologic changes in older people that increase drug susceptibility are summarized in the accompanying display, Focus on the Older Adult.

Recall **Mr. Baptiste**, the older adult receiving intravenous antibiotics for a wound infection. The nurse would need to consider age-related changes that might interfere with the drug action, and be especially alert for signs and symptoms of drug toxicity.

Weight

Expected responses to drugs are based largely on the reactions that occur when the drugs are given to healthy adults (ages 18 to 65 years, 150 lb [~68 kg]). It is important to know the usual dose for a medication before administering it. Body surface area (BSA) is the area of the external surface of the body, expressed in square meters (m^2). BSA is the initial factor considered when calculating the drug dose for infants, children, older adults, patients receiving oncologic medications, and patients with low body weight (Frandsen & Pennington, 2021; Karch, 2020). Drug doses for children are calculated by weight in kilograms or BSA.

Biologic Sex

The difference in the distribution of body fat and fluids in males and females is a minor factor affecting the action of some drugs. To date, most research on drugs and their actions and effects has been conducted on males. Future clinical drug trials are expected to include more females/women to document the effects of hormonal fluctuations, and determine the safety and efficacy of specific drugs during pregnancy (Fairlie et al., 2019).

Cultural and Genetic Factors

Religious restrictions and beliefs or cultural practices may affect the patient's acceptance of, response to, and adherence to certain drug therapies. Health care providers need an understanding of a patient's cultural values, beliefs, and practices to provide culturally competent care that reflects cultural humility (Giger & Haddad, 2020). For example, Christian Scientists place their faith in a system of spiritual healing; therefore, they do not take medicine. A Christian Scientist would not participate in a childhood vaccination program or seek pharmaceutical therapy to manage disease (The Christian Science Board of Directors, 2020). Herbal treatments that are popular in some cultures may interfere with or counteract the action of prescribed medication.

Ethnopharmacology is a relatively new field of study composed of several interrelated aspects. "Combining the approaches of medical anthropology, phytotherapy, and pharmaceutical science, this discipline examines medicinal plants in indigenous cultures, their bioactive compounds, and the sustainable development and production of nature-derived therapeutics" (Transcultural C.A.R.E. Associates, 2020, Ethno Pharmacology). Although standardized classification systems do not universally exist, discussions around ethnopharmacology and ethnomedicine involve cultural perceptions and values that impact medical systems, cross-cultural comparisons of terms and medicinal uses, and drug discovery (Bruhn & Rivier, 2019; Staub et al., 2015). The more recent use of the term *ethnopharmacology* (or *ethnic pharmacology*) involves the study of the effect of ethnicity on responses to prescribed medication, especially drug absorption, metabolism, distribution, and excretion. This is often associated with **pharmacogenetics** where differences in the responses of patients receiving the same medication may result from genetic differences, such as genetic variations in certain enzymes, that may cause differing drug responses. Ethnicity and race influence responses to certain medications. Certain ethnic groups and races have more of these variations than do others (Muñoz & Hilgenberg, 2006; Woods et al., 2017). Specifically, there may be important variations in the therapeutic dose and/or incidence of adverse effects. Some patients in certain groups obtain therapeutic responses at lower doses than those usually prescribed, while other patient groups require a larger dose to have the same therapeutic response. For example, angiotensin-converting enzyme (ACE) inhibitors have been found to more frequently cause an ACE inhibitor–induced cough in Asian American patients, and there is a higher risk of angioedema (severe swelling) with African American patients. ACE inhibitors are generally less effective with African American patients; thiazide-type diuretics and calcium channel blockers (CCBs) are more effective in controlling their hypertension (Whelton et al., 2018). Care must be taken, however, to avoid making

sweeping generalizations and assumptions. Ethnicity and race influence responses to certain medications, but no two people are alike.

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES IN DRUG RESPONSE

A ge-Related Changes	Implication or Response	Nursing Strategies
Decreased gastric motility and slowed gastric emptying; increased gastric pH	Stomach irritation; nausea and vomiting; gastric ulceration; altered absorption of drugs	• Assess for symptoms of gastrointestinal discomfort. • Assess stool for blood.
Decreased lean body mass; decreased total body water	Decreased distribution of water-soluble drugs and higher plasma concentrations, leading to increased possibility of drug toxicity	• Assess for signs of drug interactions or toxicity. • Monitor blood levels of drugs. • Monitor fluid balance—intake and output.
Increased adipose tissue	Accumulation of fat-soluble drugs; delay in elimination and accumulation of drug in the body, leading to prolonged action and increased possibility of toxicity	• Assess for signs of drug interactions or toxicity. • Monitor blood levels of drugs.
Decreased number of protein-binding sites	Higher drug plasma concentrations, leading to increased possibility of drug toxicity	• Assess for signs of drug interactions or toxicity. • Monitor blood levels of drugs. • Monitor laboratory values—albumin and prealbumin.
Decreased liver function; decreased enzyme production for drug metabolism; decreased hepatic perfusion	Decreased rate of drug metabolism; higher drug plasma concentrations, leading to prolonged action and increased possibility of drug toxicity	• Assess for signs of drug interactions or toxicity. • Monitor blood levels of drugs. • Monitor laboratory values—hepatic enzymes.
Decreased kidney function, renal mass, and blood flow	Decreased excretion of drugs, leading to possible increased serum levels/toxicity	• Assess for signs of drug interactions or toxicity. • Particularly monitor NSAID use, which may decrease renal blood flow and function. • Monitor blood levels of drugs. • Monitor laboratory values—creatinine clearance, blood urea nitrogen, serum creatinine.
Alterations in normal homeostatic responses; altered peripheral venous tone	Exacerbated response to cardiovascular drugs; more pronounced hypotensive effects from medications	• Assess for signs of drug interactions or toxicity. • Monitor blood levels of drugs. • Monitor vital signs. • Take orthostatic hypotension precautions.
Alterations in blood–brain barrier and sensitivity of receptor sites	Enhanced central nervous system penetration of fat-soluble drugs; increased possibility for alterations in mental status, dizziness, gait disturbances	• Assess for signs of drug interactions or toxicity. • Assess for dizziness and lightheadedness. • Take fall safety precautions.
Decreased central nervous system efficiency	Prolonged effect of drugs on the central nervous system; exacerbated response to	• Assess for signs of drug interactions or toxicity • Assess for alterations in

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	analgesics and sedatives	neurologic status • Monitor vital signs and pulse oximetry.
Decreased production of oral secretions; dry mouth	Difficulty swallowing oral medications	• Monitor ability to swallow medications, especially tablets and capsules. • Discuss changing medications to forms that can be crushed and/or liquid forms with prescribing practitioner.
Decreased lipid content in skin; decreased blood supply to the skin	Possible decrease in absorption of transdermal medications	• Monitor effectiveness of transdermal preparations.

Box 30-1 **Tips for Culturally Respectful Communication**

- Encourage cultural sensitivity in health care workers in your particular setting. Acquire basic information about health beliefs and practices of various cultural groups in your health care setting. This provides a basis for assessing a patient's beliefs and practices. Recognize, however, that within all cultures and ethnic groups, there are members who do not hold all the values of the group.
- Consider biologic variations (e.g., color, body structure, pharmacogenetics) when performing a baseline assessment and administering medications.
- Be alert to atypical drug responses or unexpected adverse effects that may occur in certain racial or ethnic groups. This knowledge helps you direct assessment questions as appropriate.
- Ask specifically about the use of folk or home remedies prescribed by a nontraditional healer.
- Ask specific questions about possible adverse effects, rather than asking general questions or waiting for the patient to voice concerns. For example, do not ask, "Are you having any problems with your medicine?" Instead, ask, "Have you noticed any unusual, involuntary movements?"
- Practice cultural humility. Consider individual cultural health practices, values, and definitions of health and illness when teaching patients and families. Ask, "What do you think caused your health problem?" and "What treatment do you think will help?"
- Include culturally sensitive information in all basic health teaching. For example, consider the patient's perception of time and space when teaching.
- Consider the impact of their social organization and roles when presenting information. Involve the family and other members of the community as appropriate.
- Determine the patient's language preferences for spoken and written communication. Use trained medical interpreters as needed.
- Use printed or audiovisual information that is in the language spoken by your patients. Recognize that diversity exists within cultural groups. For example, the Hispanic population includes Mexicans, Cubans, Puerto Ricans, and other Latino groups.
- Help culturally diverse patients to value and understand the importance of communicating concerns and asking questions about prescribed medications. Patients and families need to know how to identify major adverse effects of the medications they are taking and the appropriate person(s) to contact if these effects are noted.

Source: Adapted from Giger, J. N., & Haddad, L. G. (2020). *Transcultural nursing: Assessment and intervention* (8th ed.). Elsevier Inc; Muñoz, C., & Hilgenberg, C. (2006). Ethnopharmacology: Understanding how ethnicity can affect drug response is essential to providing culturally competent care. *Holistic Nursing Practice*, *20*(5), 227–234. https://doi.org/10.1097/00004650-200609000-00004; and Woods, D. L., Mentes, J. C., Cadogan, M., & Phillips, L. R. (2017). Aging, genetic variations, and ethnopharmacology: Building cultural competence through awareness of drug responses in ethnic minority elders. *Journal of Transcultural Nursing*, *28*(1), 56–62. https://doi.org/10.1177/1043659615606202.

General and specific cultural knowledge allows the health care provider to ask the right questions when interacting with patients of varying backgrounds. Nurses who are aware of the specific needs and beliefs of culturally diverse patient populations are better able to communicate effectively and provide holistic, person-centered care that reflects cultural humility. Box 30-1 gives guidelines for effective, culturally respectful communication about medication.

Psychological Factors

The patient's expectations of the medication may affect the response to the medication. A **placebo** is a pharmacologically inactive substance. In clinical drug trials, one group of patients receives the active drug, whereas another group receives a placebo to study the drug's effects. Some patients appear to have the same response with the placebo as with the active drug–this is referred to as the *placebo effect* (McCuistion et al., 2021). Psychological factors such as attitudes and expectations of drug therapy also directly impact adherence to the medication plan, especially with long-term drug therapy (Frandsen & Pennington, 2021).

Pathology

The presence of disease can affect drug action. For example, the liver is the primary organ for drug breakdown, so pathologic conditions that involve the liver may slow metabolism and alter the dosage of the drug needed to reach a therapeutic level. Drugs taken orally may be impacted if a gastrointestinal disorder interferes with absorption. Cardiovascular disorders that affect blood flow potentially impact all pharmacokinetic processes. The kidneys excrete most drugs and their byproducts from the body. Pathologic conditions that involve the kidneys would change excretion and alter the dosage of the drug required to obtain a therapeutic level. Even the endocrine system, particularly thyroid disorders, has an effect on metabolism. These types of conditions also influence the presence of adverse effects, such as toxicities.

Environment

A patient's environment may influence that individual's response to medications. Sensory deprivation and overload may affect drug responses. The patient who receives pain medication or a sedative in an active, noisy environment may not be able to benefit fully from the medication's effects; those receiving pain medication in a quiet environment and using an additional relaxation method, such as guided imagery, may benefit from the pain medication for a longer period of time. The relative oxygen deprivation at high altitudes may increase sensitivity to some drugs.

In addition, nutritional state can also affect the body's reaction to certain drugs. When dietary factors are altered, drug therapy may produce different effects in the body than would normally occur. For example, many drugs normally bind to proteins in the plasma. Lowered protein levels in the body means less drug bound to plasma proteins, which impacts on biotransformation and excretion of the drug. This leads to a higher concentration of free (unbound) drug in the body. A higher drug concentration increases the drug's effect in the body and the risk for adverse effects (Frandsen & Pennington, 2021; Karch, 2020).

Timing of Administration

The presence of food in the stomach can delay the absorption of orally administered medications. Alternatively, some medications should be given with food to prevent gastric irritation; the nurse should consider this when establishing a patient's medication schedule. Other medications may have enhanced absorption if taken with certain foods. Circadian rhythms and cycles may also influence drug action.

Drug Dose and Serum Drug Levels

Serum (blood) drug levels were reviewed earlier in this chapter in relation to drug dosage (see Absorption). The goal is to maintain a therapeutic level of a drug in the body. In addition to using serum drug levels to initiate and monitor drug therapy, they are also used to assess peak and trough levels of certain drugs, particularly antibiotics that are known to be toxic to the kidney (nephrotoxic). After a drug has been absorbed, its serum level can be monitored by drawing a blood specimen and measuring the level of the drug in the serum. A drug's **therapeutic range** is the concentration of drug in the blood serum that produces the desired effect without causing toxicity. The **peak level**, or highest plasma concentration, of the drug should be measured when absorption is complete. The peak level may be affected by factors that affect drug absorption as well as the route of administration. The peak level is typically drawn 1 hour after a drug has been administered (depending on the route). The **trough level** is the point when the drug is at its lowest concentration, indicating the rate of elimination. The trough level is typically drawn 30 minutes before the next dose is scheduled to be administered. The dosage schedule, as well as the half-life of the drug, can affect the trough level. A drug's **half-life** is the amount of time it takes for 50% of the serum concentration of a drug to be eliminated from the body. When a drug is given at a consistent dose, it takes four or five half-lives to achieve a steady concentration and develop balance between tissue and serum concentrations. This is when maximal therapeutic effects occur (Frandsen & Pennington, 2021; Karch, 2020). Monitoring these levels ensures that therapeutic ranges are obtained without reaching toxic levels.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Consider **Regina Sauder**, the adult admitted to the hospital with a DVT. She is receiving intravenous heparin and oral warfarin, both of which are monitored using blood tests. Her dose of each drug is adjusted based on the laboratory results to ensure the appropriate therapeutic effect.

Drug Legislation

In 1906, the Pure Food and Drug Act designated the U.S. Pharmacopeia and National Formulary as the official drug resource in the United States (USP-NF, 2020), which set national standards for drug quality. This act also empowered the federal government to enforce these standards. This legislation was updated in 1938 by the Federal Food, Drug and Cosmetic Act, prohibiting adulterated or mislabeled drugs from being made available. The FDA enforces this law. Extensive testing of new drugs is required before they may be marketed for use. The Durham-Humphrey amendment to the Federal Food, Drug and Cosmetic Act enacted in 1952 distinguished prescription drugs from nonprescription (over-the-counter [OTC]) drugs and provided directions for dispensing prescription drugs.

The Kefauver-Harris Amendment of 1962 increased controls on drug safety, requiring tighter testing of drugs and written inclusion in the drug literature of adverse reactions and contraindications for approved drugs. The Comprehensive Drug Abuse Prevention and Control Act, also known as the Controlled Substances Act, was passed in 1970. This law regulates the distribution of narcotics and other drugs of abuse. Such drugs have been categorized according to their therapeutic usefulness and potential for misuse or abuse (U.S. Department of Justice, Drug Enforcement Administration, 2020). Government programs for the prevention and treatment of **substance use disorder** (a term that encompasses drug/substance abuse and substance dependence/addiction) were established. In 1983, the Drug Enforcement Administration (DEA), a part of the Department of Justice, was identified as the nation's sole legal drug enforcement facility (Karch, 2020). See the Thoughtful, Person-Centered Practice: Challenging Topics (on page 924) feature for a discussion of clinical judgment as it relates to the challenging topic of patients who are drug-seeking.

Thoughtful, Person-Centered Practice: Challenging Topics

Patients Who Are Drug-Seeking

Many controversial issues make it challenging to know how to respond as a professional nurse in select scenarios. Often, the nurse's personal and/or professional values may conflict with options desired by patients, families, employers, and communities. Not infrequently, nurses have to make clinical judgments, balancing promoting and safeguarding personal integrity and respecting the values and preferences of patient. The *Essentials* for entry-level professional nursing education, a document that guides curriculum development and outcomes, identifies a competency within Domain 9 (Professionalism) focused on demonstrating "awareness of personal and professional values and conscious and unconscious biases" (p. 57). The *Essentials* also addresses biases in Domain 10 (Personal, Professional, and Leadership Development) with respect to self-awareness and "developing capacity for leadership" (p. 59) and in Domain 6 (Interprofessional Partnerships) in relation to the "mutual respect and communication" (p. 47) required when working with other professions (AACN, 2021).

Read the scenario below and see if you can articulate what you believe, why you believe this, and how these beliefs are likely to inform the decisions you make and your behavior, especially when you are confronted with competing obligations. Based on Tanner's Clinical Judgment Model (2006), consider reflection-in-action and reflection-on-action (Nielson, Stragnell, & Jester, 2007):

Reflection-in-Action

As you read, consider what the new nurse is thinking in the moment—what happened? How did the patient, family, and health care provider respond? What did the nurse do next?

Scenario

As a new graduate nurse in residency in a busy Emergency Department (ED), I wouldn't be doing triage for some time, but the team assigned me to the triage nurse for the day to assess my progress and hone my assessment skills. With the support of the very experienced triage nurse, I had appropriately (and

quickly) identified a *Code Stroke*, wrapped a laceration while comforting both the father and child, and expedited the admission of a patient undergoing cancer treatment who had spiked a fever. The flow of patients was steady, which kept us busy, but I noted occasional muffled crying coming from what I thought was a middle-age woman in the corner of the room. She had already been triaged by my preceptor, but I had stepped away during the interaction and didn't know the full story. Between patients, I asked the triage nurse, "What's going on with the woman who is crying? I can't see her face because she's got a blanket over her head, but I can hear her periodically crying. Should I check on her again…bring her back for re-assessment?" The triage nurse rolled their eyes in response. I followed-up with, "What am I missing?" The triage nurse explained, "She's reporting severe, unexplained pain in her back. Her assessment is totally unremarkable. She verbalized the need for IV Dilaudid because nothing else works. That's three red flags." In that moment, I realized that I still had a lot to learn regarding how to synthesize information obtained subjectively from the patient and objectively from the health care professional. The triage nurse encouraged me to go do a re-assessment and report back. I centered myself, considered my personal biases, thought about what I knew about drug-seeking behavior, and approached the patient in the now-empty waiting room.

Effective Noticing (Cues)

1. What did you notice about the situation initially? What information/observations are significant? What information deviates from what is expected/normal/usual?

Effective Interpreting

2. How would you prioritize this data? What other assessment data, evidence and/or information would you need to consider the situation? How would you obtain this additional information?
3. What do you think about this situation? Consider personal and previous nursing experiences that you have had and formal knowledge (physiology, psychology, communication skills) that may be of assistance in providing care in this situation.

Scenario

I chose to give the patient the benefit of the doubt and tried hard to ignore the seeds planted by the triage nurse—there was a good chance this patient was really in pain and needed medical intervention. As I approached the patient, I could hear her talking on the phone: she was laughing and very interactive with the person on the other end of the call. Since her head was under the blanket, and she did not respond to my verbal requests for attention, I briefly touched her arm to get her attention. She immediately uncovered her head, told the person on the phone she would call them back, and grabbed her lower back, wincing in pain. I appreciate that the experience of pain is individual and the experience is what the patient says it is, so I proceeded with my assessment. The patient reported new onset, sudden back pain and requested hydromorphone (Dilaudid) IV. I let her know that I was the nurse performing the triage assessment and could not prescribe any medications. I indicated that, based on our assessment, it was likely going to be an hour wait, but that we would get her back to a room as soon as possible. She began to moan loudly and stood up, verbalizing that she "didn't deserve to be treated this way." The patient approached another nurse walking through the waiting room, who briefly engaged with the patient and then gestured to me to meet him behind the nurse's station with the triage nurse. As the three of us came together, the nurse who was approached by the patient in the waiting room revealed that he knew this patient from the other EDs where he picked up shifts, and that the patient was flagged as drug-seeking and prescriber-shopping in the system. I listened but asked if I could go finish my interaction with the patient before making my final clinical judgment. As I entered the waiting room, I realized that the blanket was on the floor, and the patient was gone.

Reflection-in-Action

Now, consider the nurses' decisions and reflect on your learning. See if you can articulate what you believe, why you believe this, and how these beliefs are likely to inform the decisions you make and your behavior, especially when you're confronted with competing obligations.

Effective Responding

4. How would you describe the obligations you have in this scenario to your patient, to yourself, to your team, and to the community?
5. If you cannot fulfill each of these obligations how will you prioritize them? What basis/rationale do you use for prioritization? Remember that the ANA *Code of Ethics for Nurses* reminds us that "health is a universal right," which includes access to emergency care. Has this patient received adequate access through the triage process?
6. What policies, procedures, and guidelines could you use in this specific situation? What are the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

requirements regarding reporting and follow-up at the hospital, local, and national level?

Effective Reflecting

As you think about this case, is your assumption that the patient left to seek treatment elsewhere because she needed timely intervention for her indescribable pain that she did not think she would get in your ED or because she realized that she had been outed as drug-seeking? As nurses, we have to differentiate between making assumptions or viewing patients as stereotypes, and using our experience to inform our clinical judgment.

7. Do you think the triage nurse used their experience to inform their decision or was it based on a jaded response or assumption? Did the triage nurse provide adequate support/rationale for their decision?
8. Do you agree with the criteria the nurse used to evaluate their decision? How do you evaluate your clinical and moral judgments?
9. What resources can you access to better inform your decision?
10. What personal attributes and competencies are most likely to lead to a good response?

Reflection-on-Action

Then look back at the scenario and reflect on your learning—how might this have been different if you did not have the additional information from the third-party nurse who happened to walk through the waiting room? How did your knowledge and/or skills expand based on this scenario? What attitude, value, or belief shifts did you experience (if any) after reading this scenario? What would you do differently if you were in this situation? What more do you need to know to be able to manage this or a similar situation in the future?

More current drug-related legislation includes the Food and Drug Administration Modernization Act of 1997. This act provides for accelerated review and use of new drugs and approves drug testing in children before marketing. In addition, it necessitates the inclusion of clinical trial data for experimental drug use for serious or life-threatening health conditions and requires drug companies to provide information related to *off-label* drugs (drugs not approved by the FDA), including their uses and costs. The act requires that drug companies planning to discontinue drugs must inform health professionals and patients at least 6 months before stopping drug production (McCuistion et al., 2021).

In 2003, the Pediatric Research Equity Act was signed into legislation. This act authorizes the FDA to require testing by drug manufacturers of drugs and biologic products for their safety and effectiveness in children. Drug manufacturers must not assume that children are small adults (McCuistion et al., 2021). Also in 2003, Congress approved the Medicare Prescription Drug Improvement and Modernization Act (MMA). This legislation provides financial assistance to seniors to purchase needed prescription medications.

PRINCIPLES OF MEDICATION ADMINISTRATION

Medication Prescriptions and Orders

Prescription and *order* both refer to the means by which a provider communicates information regarding medications (and other procedures and therapies) to the health care team. When considering medication administration, both terms refer to a prescription written or entered into the EHR by a provider with prescriptive rights. In health care, the word *order* is typically used in the inpatient setting, with *prescription* primarily used in the outpatient and community settings. No medication may be given to a patient without a medication order from a licensed practitioner. Each health facility has a policy specifying the manner in which the practitioner writes an order. In some instances, prescriptions are written on a form designed specifically for a primary care provider's order. This becomes part of a patient's permanent record. Prescribers are able to make use of electronic prescribing systems, sending medication prescriptions electronically to outpatient pharmacies. Most health care facilities are beginning to use computer provider order-entry (CPOE) systems. CPOE systems allow the prescribing provider to enter medication orders in a standard format. CPOE systems guide the prescriber in complete, accurate, and appropriate prescribing. The computer sends the prescription directly to the pharmacy and enters the prescription into the patient's permanent record. This prevents any guessing when handwriting is illegible or drug names are similar (Frandsen & Pennington, 2021). Some of the information this system provides includes recommended dosing of medications, drug-specific information, current patient information, laboratory tests that monitor the action of the drug, and potential interactions that may occur with other medications or food. A CPOE system can make medication administration safer and reduce ADEs.

Safe practice dictates that a nurse follows only a written order or an order entered into a CPOE system because these

types of orders are less likely to result in error or misinterpretation. Under certain circumstances, such as in an emergency, a verbal order from the prescribing provider may be given to a registered nurse or a pharmacist. In most settings, a student nurse is not permitted to accept a verbal order from a provider. The legal implications for dispensing and administering an agent without a written order vary, and nurses must be familiar with the exact facility policy whenever called on to administer therapeutic agents. The legal implications of verbal orders are discussed in Chapter 7.

Usual hospital policy dictates that when a patient is admitted, unless specific orders to the contrary are written, all drugs that may have been prescribed while the patient was at home are discontinued. To avoid the possibility of having the patient continue to take the home medications while receiving the same ones or others under new orders, all medications should be sent home with the family or removed from the patient's bedside. In some inpatient facilities, patients keep their medications at their bedside and learn, or continue, to administer them as they would at home. It is believed that this approach helps to promote patients' independence. This practice is also seen with drugs that are not available at a health care institution (such as oral contraceptives and certain antidiabetic agents). Careful labeling and adherence to institution-based policies and procedures must be ensured. Nurses continue to be involved with the medication self-administration process, verifying the medications are understood by the patient, are taken appropriately, and that the medications are documented in the patient's permanent record.

When a patient has had surgery, is transferred to another clinical service, is transferred to another health facility, or has any other transition in care, it is a general practice that all orders related to drugs are discontinued and new orders are written in the new setting. **Medication reconciliation** is a process used by the health care team where the current medication orders are compared to patient report, the patient's medical record, and prescriptions that may have been in place prior to the transition of care (Barnsteiner, 2008). Although most often a responsibility of the nurse, pharmacists and other members of the health care team play a valuable role in the medication reconciliation process (Choi & Kim, 2019; Fernandes et al., 2020). The Joint Commission (2020a) includes medication reconciliation as part of the 2020 National Patient Safety Goals. Goal 3 identifies the collection of a patient's current medication list, informing patients of the importance of maintaining an accurate medication list, and comparison of medications taken with the newly prescribed medications to prevent duplications, omissions, or interactions (The Joint Commission). Implementation of medication reconciliation, especially at times of transitions in care, remains best practice despite the relative lack of evidence that medication reconciliation directly reduces the rate of ADEs or directly affects other patient outcomes (Anderson et al., 2019; Redmond et al., 2018; Rose et al., 2017; Tamblyn et al., 2019). Ideally, medication reconciliation involves more than simply a review of the medication lists. Reconciliation should address: (1) ensuring agreement among the clinicians on the patient's health care team, (2) ensuring agreement between the patient and clinician(s), (3) deprescribing any unnecessary medications, (4) decreasing the complexity of medication regimens to decrease patient burden and increase adherence, (5) assessing the cost of medications and out-of-pocket expenses, and (6) communicating with all involved health care team members (Rose et al., 2017). Standardization of the processes inherent in medication reconciliation is needed to support adequate measurement and targeted quality improvement initiatives (Rose et al., 2017; Rungvivatjarus et al., 2020; Zimmerman et al., 2017).

Types of Orders

There are several types of orders that a prescriber may write. A *routine order* is carried out as specified until it is canceled by another order. Many practitioners whose practices are limited to a particular clinical area have a specified set of written orders for all their hospitalized patients. These are also referred to as *standing orders*. A practitioner may write a routine or standing order with specified limitations; that is, the prescriber specifies that a certain order is to be carried out for a stated number of days or times. After the stated period has passed, the order is discontinued automatically.

The prescriber may write a **PRN order** (*as needed*) for medication. The patient receives medication when it is requested or required, and when the specifics of the order (particularly clinical parameters and timing between doses) are met. PRN orders are commonly written for the treatment of symptoms. For example, medications used for pain relief, to relieve nausea, and for sleep aids are often written as a PRN or as-needed order.

Another type of order is the *one-time* order. With this type of order, the directive is carried out only once, at a time specified by the prescriber. Medication to be administered immediately before surgery is an example of a one-time order. A **stat order** is also a single order, but it is carried out immediately. A stat order for a bronchodilator or an antihistamine would be carried out immediately for a patient who is experiencing an anaphylactic drug reaction.

Parts of the Medication Order

The medication order consists of seven parts:

. Patient's name and a secondary identifier (date of birth, medical record number)
. Date and time the order is written
. Name of drug to be administered
. Dosage of the drug
. Route by which the drug is to be administered
. Frequency of administration of the drug

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

. Signature of the prescribing provider

Medication orders require the drug, dose, rate, route, frequency, and, when appropriate, duration to be explicit and specific to the needs of the patient in order to achieve the desired outcome. Although not to be used for identifying a patient, inpatient orders also contain information regarding the patient's location, such as unit and room number (Bowen, 2016).

PATIENT'S NAME AND A SECONDARY IDENTIFIER (DATE OF BIRTH, MEDICAL RECORD NUMBER)

The patient's full name is used. The middle name or initial should be included to avoid confusion with other patients. In facilities using paper records, the patient's full name, secondary identification number, and the primary care provider's name are labeled on all sheets on the patient's chart, including the medical order sheet. Be extremely careful when administering medications when there is more than one patient on the unit with the same last name. Not only can the nurse give the wrong patient the wrong medication, but a provider may enter an order in the wrong patient's medical record. A secondary identifier is used when verifying the patient's identity. If using the date of birth as a second identifier, the day, month, and year should all be included.

DATE AND TIME THE ORDER IS WRITTEN

The date and time the order is written are provided. Because the nursing staff in inpatient facilities changes several times during each 24-hour period, the date and time help to prevent errors of oversight as different nurses take charge of the patient's care. When an order is to be followed for a specified number of days, the date and time are important so that the discontinuation date and time can be determined accurately. State law determines the length of time an order for a narcotic remains valid, so the starting date and time must be clearly documented. Hospitals are utilizing many computer applications in patient care. Examples of such technology include a computer-generated database, computer-generated medication administration orders, and computer-generated flow sheets, as well as EHRs. This technology is helping to improve patient safety, but it also requires that nurses monitor the computer system for patient updates, including new medication orders.

NAME OF DRUG TO BE ADMINISTERED

The name of the drug is stated in the order, either by the trade (brand) name and/or by the generic name. Certain brand names are well known, but the practice of using the generic name is considered safest and is required by many health care facilities.

A nurse unfamiliar with a drug can use several sources to obtain information. The USP-NF (2020) is the official source in the United States. Most other countries have similar references that describe official therapeutic agents. Most facilities also provide their own formulary, listing the drugs stocked by the facility. Health care facilities also provide access to online medication information sites. The *Physicians' Desk Reference* (PDR) is another source of information that is supplied by pharmaceutical companies. In addition, information about drugs can be obtained from the hospital pharmacist, the prescriber, and any of several texts written specifically for the nursing role in the management of drug therapy. Many of these nursing-specific texts are available as software and can be loaded onto handheld devices such as tablets and smartphones.

DOSAGE OF THE DRUG

The dosage of a drug can be stated in either the metric or the household system. These systems are described in the Dosage Calculations section. The metric system has been adopted internationally, is the most widely used, and is the safest measurement system for drug dosages. Self-administered drugs are commonly labeled in household measurements to facilitate administration for the patient. The household system of measurement may also be used in community settings, such as a person's home (McCuistion et al., 2021). It is important to be familiar with common equivalent measurements when using household equipment, such as teaspoons and tablespoons, because the home is usually not equipped with special measuring devices. If administration equipment is not available, instruct patients to use measuring spoons and *not* silverware, due to the variability of the amount silverware can hold. The most common equivalents are in Appendix B. However, to prevent errors, best practice requires providing patients with commercially available oral syringes, droppers (infants), and cups printed with easy-to-read volumes using only the metric scale (Institute for Safe Medication Practices, 2020).

Certain standard abbreviations are used to indicate drug amounts; it is important to know the common abbreviations before administering drugs. Refer to Box 20-3 in Chapter 20 for common abbreviations used in drug orders. Several abbreviations used in the past have been identified as having the potential to cause errors. The Joint Commission has identified an official *do not use* list of abbreviations. See Table 20-3 on page 528 for this list. The use of ambiguous medical abbreviations has been identified by the Institute for Safe Medication Practices (ISMP) and the FDA as one of the most common but preventable sources of medication errors (ISMP, 2017). Refer to the website for the ISMP at https://www.ismp.org/Tools/abbreviations for more information about their campaign to eliminate the use of error-prone abbreviations. In addition, the ISMP has identified a list of error-prone abbreviations, symbols, and dose designations that should never be used when communicating medical information (ISMP, 2017). See Table 20-2 for this list.

Table 30-2 Routes for Administering Drugs

TERMS USED TO DESCRIBE ROUTE	HOW DRUG IS ADMINISTERED
Oral route	Having patient swallow drug
Enteral route	Administering drug through an enteral tube
Sublingual administration	Placing drug under tongue
Buccal administration	Placing drug between cheek and gum
Parenteral route	Injecting drug into the body
Subcutaneous injection	Subcutaneous tissue
Intramuscular injection	Muscle tissue
Intradermal injection	Corium (under epidermis)
Intravenous injection	Vein
Intra-arterial injection	Artery
Intracardial injection	Heart tissue
Intraperitoneal injection	Peritoneal cavity
Intraspinal injection	Spinal canal
Intraosseous injection	Bone
Topical route	Applying drug onto skin or mucous membrane
Vaginal administration	Vagina
Rectal administration	Rectum
Inunction	Rubbing drug into skin
Instillation	Placing drug into direct contact with mucous membrane
Irrigation	Flushing mucous membrane with drug in solution
Skin application	Applying transdermal patch
Pulmonary route	Having patient inhale drug

ROUTE OF ADMINISTRATION

The route to be used when administering a medication is stated clearly because some drugs can be given in more than one way, and others may be used safely through only one route. The route also affects the absorption of drug. Table 30-2 describes common routes by which medications are administered. Refer to The Nursing Process for Administering Medications beginning on page 935 for guidelines on administering drugs by these routes.

FREQUENCY OF ADMINISTRATION

The time and frequency with which a drug is to be administered are usually stated in standard abbreviations in the medication order. Keep in mind that only approved abbreviations are used, and care is taken to not use old abbreviations that have been phased out due to error and safety concerns (see Table 20-3 on page 528). Common abbreviations used in writing prescriptions, including time and frequency, are listed in Box 20-3 on page 524.

The nursing service, facility policy, and pharmacy departments of inpatient facilities usually determine the hours at which routine drugs are given. To lessen the risk for error, many health care facilities use the 24-hour clock (or military time), which designates midnight as 0000 hours and runs until 2400 hours. For example, an every-4-hour drug administration may be at the times of 1200, 1600, 2000, 0000, 0400, and 0800. Another facility may use the hours 1300, 1700, 1900, 0100, 0500, and 0900. If an administration order states that the drug is to be given before or after meals, the time of administration depends on the hours at which meals are served. It is a nursing and pharmacy responsibility to check that times for medication administration correspond to safe practice for that drug.

If a drug is to be given only once or twice a day, the decision about which hours to use depends on the nature of the drug and the patient's plan of care, as well as the standard facility administration times. Whenever possible, consider the patient's choice of time.

Administer drugs punctually, as ordered. A nurse administering medications to several patients cannot reasonably

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

give all of the medications to all of the patients exactly on the hour indicated. Facility policies vary, but a common one is that drugs should be administered within a half-hour before or after the indicated hour. Thus, a drug to be administered at 0900 can be administered any time between 0830 and 0930 using this policy. However, it is important to note that this policy does not apply to all drugs. A preoperative medication ordered to be given at 0730 should be administered at that hour because the time was planned in relation to the time that surgery is to begin. Preoperative medications may also be given when the nursing unit receives a call from the operating room to premedicate the surgical patient. This also holds true when patients are given drugs before certain diagnostic procedures and with stat orders.

SIGNATURE OF THE PRESCRIBING PROVIDER

Prescribers using a CPOE access the system using a unique username and password. The identifying information of the prescribing provider, such as name and title, is automatically recorded when the system is accessed, and a handwritten signature is not necessary. When it is necessary to handwrite a prescription, the signature, title, and identifiers (such as the DEA or National Provider Identifier [NPI] numbers) of the prescriber must accompany the order. Many facilities require prescribers to also include their printed name and address with the signature, to facilitate contacting the prescriber as needed.

This identifying information is important for legal reasons because the authority to prescribe drugs is defined by state laws. Also, if there is a question about the prescription, the identifying information indicates who should be contacted.

Checking the Medication Order

Facility policy specifies the manner in which the medication order is checked. Various systems are used; nurses should be familiar with the system used in the facility where they work and should use it as trained to minimize errors.

The patient's medication record, often called an MAR (medication administration record) is a complete list of all medications prescribed for the patient. Increasing numbers of health care facilities are computerizing patient records, including medication records (eMARs [electronic medication administration record]). The nurse is responsible for checking that the medication order was transcribed correctly by comparing it with the original order, depending on the type of system in use. The nurse is also responsible for double-checking the dosage and appropriateness of the medication.

Questioning the Medication Order

Nurses are legally responsible for the drugs they administer. Therefore, it is important to question any drug order suspected to be in error. The suspected error may be in any part of the order. A study of neonatal nurses in Australia identified several things that impact on nurses questioning an order, including the working environment (whether positive or negative), their perceived responsibility to do the right thing, and their knowledge about medications (Aydon et al., 2016). When preparing to administer a medication, ask yourself why the patient is receiving the medication—is there a rationale you can provide as to why this medication has been prescribed? Do the therapeutic and pharmacologic classes link with your patient's condition(s)? If not, then ask the provider or pharmacist, and/or use an appropriate resource to further investigate. Perhaps the provider inadvertently prescribed the wrong medication—the only way to be sure is to ask. Take the time to look up the medication, especially if it is one you do not use on a daily basis, and consider whether the dose, route, frequency, and prescribed use are within the range of what your resource lists. Once in practice, nurses tend to become familiar with medications used frequently with the patient populations they serve, but learning what is a *reasonable* dose takes time and experience. There are potential legal implications if a medication error occurs when, based on education and experience, the nurse should have noted and reported the error. Confusion over the placement of a decimal point can lead to a medication error. A zero should always precede a decimal point (e.g., 0.1 mg) for clarity. The use of a trailing zero (e.g., 1.0) is not considered good practice and has been included in The Joint Commission's *Do not use* list. See Table 20-3 on page 528 for additional abbreviations included in this list.

A drug to which the patient is allergic may be prescribed inadvertently. In health care facilities, the allergy is listed in the chart/EHR, specifically on the eMAR/MAR, and may also be linked to the computerized medication dispensing system. The patient may wear a wristband (often red) that indicates specific allergies, so be sure to check for this when you first identify the patient. Before administering a medication, best practice is to question the patient about ever having received the medication and ask whether the patient is aware of any reaction to the medication. The patient may describe past adverse reactions with the drug. If the nurse suspects an undocumented allergy, the nurse should not give the drug and notify the provider. An allergic reaction can be life threatening to the patient.

In addition, a drug may be prescribed that would potentially interact with another medication the patient is taking. It is important that nurses verify all medications that they are unfamiliar with before administration to avoid possible drug interactions. If a nurse has difficulty deciphering a prescription, guessing is gross carelessness; checking with the provider who wrote the prescription is the only safe procedure.

Nurses have the right to refuse to administer any medication that, based on their knowledge and experience, may be harmful to the patient. Although this situation seldom occurs, it is important to understand that the patient's safety is a primary objective in the administration of medications. Always notify the primary care provider of the refusal to administer any medication. Document any concerns regarding medication orders in the patient's medical record, and note having contacted the primary care provider, the response of the primary care provider, and any related

interventions. A standardized interprofessional approach to medication administration coupled with an emphasis on patient safety creates an environment that supports the nurse questioning an order, which may directly impact on patient outcomes.

Medication Supply Systems

Medications are supplied in a number of ways. Many facilities make use of one or more systems in conjunction with each other, or variations of systems. Unit dose dispensing on a patient-specific basis is now the standard of practice for most hospitals. Pharmaceutical manufacturers provide all medications in health systems in unit dose packages that are labeled with readable medication information and computer scannable bar-coding that includes the medication's unique identifier, lot number, and expiration date (American Society of Health-System Pharmacists [ASHP], 2009). Computerized automated dispensing cabinets are a technology based on stock supply of unit dose medications. A large cabinet containing stock medications for the unit is used. The nurse accesses the system with a user name and password, pulling up a medication list for a specific patient or a list of available medications. In many systems, only medications entered for a specific patient are available for withdrawal at any one time. A computerized medication dispensing system is shown in Figure 30-1 on page 930. With an individual unit dose supply system, each patient is supplied with the medication needed for a period of time. The nurse is responsible for accurately obtaining the prescribed medications from the patient's supply. In the unit dose system, the pharmacist simplifies medication preparation by packaging and labeling each dosage for a 24-hour period.

Some nursing units use a medication cart for the administration of medications. The standard cart contains individual drawers into which the medications for each patient are placed. If computers are not standard in every patient room and an EHR is used, there may also be a computer attached to the cart that allows for ready access to the eMAR by the administering nurse. The nurse moves the cart from room to room when dispensing medications.

FIGURE 30-1. Computerized medication dispensing system.

Bar-code medication administration (BCMA) involves a computerized bar-coded administration system, where each patient and each nurse is identified by a unique bar code. Each drug is also packaged with a bar code that includes its unique National Drug Code number to identify the form and dosage. The nurse scans their own ID, the patient's ID, and each package of medication to be administered. The system confirms the nurse's dispensing authority and the patient's ID, matching the patient with their medication profile. If any of the information is incorrect or does not match, an alert message will appear on the screen notifying the nurse of the discrepancy. The system also records the medication administration and stores the information (ASHP, 2009). The implementation of BCMA technology has the potential to reduce administration errors not related to timing, errors associated with transcription of orders, and total medication errors (Shah et al., 2016).

Technology Alert

Bar-Code Medication Administration (BCMA)

BCMA uses bar-code technology to provide a safeguard against human error. Although BCMA has contributed to a reduction in medication errors, work-arounds that deviate from institution policy and procedures need to be addressed. Identification of best-practice workflow needs to be compared to actual bedside observed workflow using processes such as root cause analysis (see Chapter 28). Clinical nurses

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

must be engaged in the process of identification and removal of barriers to BCMA best practice and work to establish a culture of safety. Reinforcement and support by nurses' social networks in the clinical environment can positively affect nurses' compliance with appropriate use of BCMA (Yuan et al., 2020).

Dosage Calculations

Systems of Measurement

Nurses need to be proficient in the use of weights and measures as well as systems of measurement to calculate drug dosages and prepare medications for administration. Two systems of measurement are used in the United States for administering medications: the metric system and the household system. The apothecary system was used infrequently in the past and is no longer used for measurement of medications (McCuistion et al., 2021). The nurse may be called on to convert dosages from metric to household and household to metric. It is extremely important to be able to calculate commonly used equivalents, as listed in Appendix B. Practice the Medication Calculation Problems at the end of this chapter to develop your dose calculation skills.

METRIC SYSTEM

The metric system is the most widely accepted and convenient system of measurement. The basic units of measurement are the meter (linear), the liter (volume), and the gram (weight). The metric system is a decimal system, in which each unit can be divided into multiples of 10 (10, 100, 1,000). Calculations in the metric system often involve moving the decimal point to the right or left. In the preparation of medications, the following metric units are typically used:

Weight

- 1 kilogram = 1,000 grams
- 1 gram = 1,000 milligrams
- 1 milligram = 1,000 micrograms

Volume

- 1 liter = 1,000 milliliters or cubic centimeters

It may be necessary to convert drug dosages to a different unit in the metric system. To convert a larger unit into a smaller unit, move the decimal point to the right (the new number is larger than the original). To convert a smaller unit into a larger unit, move the decimal point to the left (the new number is smaller than the original). *Example 1:* 0.5 g equals how many milligrams? Move the decimal point three places to right; the answer is 500 mg. *Example 2:* 900 mg equals how many grams? Move the decimal point three places to the left; the answer is 0.9 g.

HOUSEHOLD SYSTEM

The household system is not widely used except in some community settings, such as a person's home. Teaspoon and tablespoon are commonly used household measures. The household system is not as accurate as the metric system because of the lack of standardization of spoons, cups, and glasses. The measurements are approximate, so the National Council for Prescription Drug Programs (NCPDP, n.d.) and other entities (American Academy of Pediatrics, 2015) advocate for the transition to the metric system in the United States for all dosing. Until this occurs, nurses need to reinforce that a teaspoon is considered to be equivalent to 5 mL. Three teaspoons equal one tablespoon. One ounce is considered to be equivalent to 30 mL. As discussed previously, teaspoon and tablespoon refer to measuring spoons, not silverware.

Methods for Computing Drug Dosages

Drugs are sometimes prepared and supplied in the amount ordered by the prescriber, and the nurse can see when checking the medication label that no calculation is necessary. At other times, drugs are not prepared and supplied in the exact quantities called for in the medication order, and the nurse must do a dosage calculation to determine what quantity of medication the patient is to receive.

FORMULA METHODS

Several formulas can be used to calculate drug dosages. One such formula consists of ratios to set up a proportion and can be used to calculate dosages for both solid and liquid preparations. A ratio shows the relation between numbers. A proportion contains two ratios. The nurse is usually seeking the quantity of on-hand medication that is equal to the desired dosage (the dosage ordered). The formula is as follows:

$$\frac{\text{dose on hand}}{\text{quantity on hand}} = \frac{\text{dose desired}}{x\ (\text{quantity desired})}$$

The dosage must be in the same unit of measurement. This applies to the quantity as well. Dosages are on the top line of the proportion, quantities on the bottom line. After the numbers are placed in the proportion, cross-multiply to find the

desired quantity. The benefit of this method is that it is predictable and easy to recall: "I have 250 mg in 5 mL and I need 625 mg in I-don't-know-how-many mL." The proportion method of calculation works best with simple calculations.

Example: Amoxicillin, 625 mg PO, is ordered. It is supplied as a liquid preparation containing 250 mg in 5 mL. How much does the nurse administer?

$$\frac{250\ \text{mg}}{5\ \text{mL}} = \frac{625\ \text{mg}}{x\ \text{mL}}$$

Cross multiply:

$$250x = 3{,}125$$

Isolate x:

$$\frac{250x}{250} = \frac{3{,}125}{250}$$

$$x = 12.5\ \text{mL}$$

Remember to *Drag-the-Tag* (the measurement associated with the x from the beginning formula)

Follow the standard rounding rules: For numbers >1, round to the 10th (tenth); for numbers <1, round to the 100th (hundredth).

Example: Digoxin 0.125 mg PO daily is prescribed. It is available as a liquid in a unit dose container labeled 500 mcg/10 mL. How many mL does the nurse administer? There are two systems of measurement in this problem and conversions cannot be built into this formula, so the conversion must take place before using the proportion method. The nurse knows that 1 mg is equal to 1,000 mcg; therefore, 0.125 mg equals 125 mcg.

$$\frac{500\ \text{mcg}}{10\ \text{mL}} = \frac{125\ \text{mcg}}{x\ \text{mL}}$$

Cross multiply:

$$500x = 1{,}250$$

Isolate x:

$$\frac{500x}{500} = \frac{1{,}250}{500}$$

$$x = 2.5\ \text{mL}$$

Drag-the-Tag

Follow the standard rounding rules: For numbers >1, round to the 10th (tenth); for numbers <1, round to the 100th (hundredth).

Another formula that can be used to calculate drug dosages is as follows:

$$\frac{\text{dose desired}}{\text{dose on hand}} \times \text{quantity on hand} = \text{desired quantity}$$

Using this formula, the previous example would be solved as:

Don't forget to multiply by quantity on hand.

$$\frac{125\ \text{mcg}}{500\ \text{mcg}} \times 10\ \text{mL} = x$$

$$\frac{125\ \cancel{\text{mcg}}}{500\ \cancel{\text{mcg}}} \times 10\ \text{mL} = 2.5\ \text{mL}$$

The mcg will cancel, leaving mL for labeling the answer.
Follow the standard rounding rules: For numbers >1, round to the 10th (tenth); for numbers <1, round to the 100th (hundredth).

This formula can be used for both liquid dosages and fractions of tablets. However, this formula can lead to errors if the carrier (10 mL in the example above) is not 1. The proportion (above) and dimensional analysis (below) methods are recommended.

DIMENSIONAL ANALYSIS

Another method that is used to compute medication dosages is dimensional analysis. Dimensional analysis, also known as factor-labeled method, is a systematic, straightforward approach to setting up and solving problems that require conversions. It is an excellent way to approach medication math because it can be used with both simple and complex

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

medication calculations. A standard approach in chemistry, dimensional analysis is a way of thinking about problems that can be used when conversions are needed to move from an order to a dose. When using dimensional analysis, the first numerator must be what you are solving for, with the remaining part of the equation working to cancel out all unnecessary content. For instance, in the amoxicillin example, you would set up the equation like this:

$$\text{mL} = \frac{5\ \text{mL}}{250\ \text{mg}} \times \frac{625\ \text{mg}}{1}$$

$$\text{mL} = \frac{5\ \text{mL}}{250\ \cancel{\text{mg}}} \times \frac{625\ \cancel{\text{mg}}}{1} = 12.5\ \text{mL}$$

Dimensional analysis can also include conversion factors in the same calculation. For instance, the nurse is to administer 50 mcg fentanyl. The pharmacy supplies the nurse with an ampule of fentanyl 0.1 mg/2 mL. How much should the nurse administer? To solve the problem, the mg needs to be converted to mcg. This can all be done in the same calculation with dimensional analysis.

Conversion from mcg to mg.

$$\text{mL} = \frac{2\ \text{mL}}{0.1\ \text{mg}} \times \left(\frac{1\ \text{mg}}{1{,}000\ \text{mcg}}\right) \times \frac{50\ \text{mcg}}{1}$$

$$\text{mL} = \frac{2\ \text{mL}}{0.1\ \cancel{\text{mg}}} \times \frac{1\ \cancel{\text{mg}}}{\overset{20}{\cancel{1{,}000}}\ \cancel{\text{mcg}}} \times \frac{\overset{1}{\cancel{50}}\ \cancel{\text{mcg}}}{1} = \frac{2\ \text{mL}}{2} = 1\ \text{mL}$$

Here is an example of what the starting formula would look like in the more traditional chemistry format:

2 mL	1 mg	50 mcg
0.1 mg	1,000 mcg	1

Pediatric Calculations

According to Kyle and Carman (2021), the most common method for calculating pediatric medication doses is based on body weight, due to the wide range of size differences from infants to toddlers to school-age children. The recommended dosage is usually expressed as the amount of drug to be given over a 24-hour period (mg/kg/day) or as a single dose (mg/kg/dose). When calculating pediatric drug dosages, check whether the prescribed amount is per dose or per 24-hour period. A medication overdose can occur if the nurse does not note that the calculation is per 24 hours and gives the total amount of medication in one dose. Weigh the child and, if necessary, convert the weight into kilograms by dividing the child's weight in pounds by 2.2 to compute the equivalent kilograms of weight. Then multiply the child's weight in kilograms by the prescribed dose to obtain the appropriate dose for the child. A drug reference book will identify the safe dose range for pediatric drug dosages based on weight.

Using Safety Measures While Preparing Drugs

The National Coordinating Council for Medication Error Reporting and Prevention (2020, para. 1) states,

> A medication error is any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer. Such events may be related to professional practice, health care products, procedures, and systems, including prescribing, order communication, product labeling, packaging, and nomenclature, compounding, dispensing, distribution, administration, education, monitoring, and use.

Medication errors can occur with almost any type of drug. Errors are more common with certain classes of medications, such as analgesics, antibiotics, anticoagulants, chemotherapeutic agents, diabetic medications, and cardiovascular agents. This is thought to possibly be due to the pharmacologic properties of the drugs that result in more adverse effects, toxicities, and interactions. Medication errors are also common in drugs with narrow therapeutic levels and in drugs prescribed frequently (Frandsen & Pennington, 2021). Safety is of the utmost importance in preparing and administering medications. There are many interventions that can minimize the risk for medication errors. The following is a discussion of nursing interventions to reduce this risk.

Three Checks and the Rights of Medication Administration

Use of the three checks and the rights of medication administration when administering medications can assist with safe administration of medications. The use of the previously discussed technology, such as bar-code medication administration (BCMA) and medication dispensing systems, does not relieve the nurse of responsibility for ensuring safe

medication administration. Check the label on the medication package or container three times during medication preparation and administration. The label should be read:

- **When the nurse reaches for the unit dose package or container**
- **After retrieval from the drawer and compared with the eMAR/MAR, or compared with the eMAR/MAR immediately before pouring from a multidose container**
- **Just before giving the unit dose medication to the patient, or when returning the multidose container**

Figure 30-2 illustrates the comparison of a medication label with the eMAR (second label check) to ensure accuracy.

The rights of medication administration can help to ensure accuracy when administering medications. However, the ISMP (2007) reiterated a position taken in 1999 that, the rights of medication administration "are merely broadly stated goals or desired outcomes of safe medication practices that offer no procedural guidance on how to achieve these goals" (para. 1). The rights themselves do *not* ensure medication safety. The nurse assumes individual accountability for safe drug administration by collaborating with the patient and interprofessional team, and engaging in behavior that follows the standards of practice defined by the institution to achieve the goals of the rights (Frandsen & Pennington, 2021; Hanson & Haddad, 2020). Suggested rights of administration vary slightly between references, with anywhere from the classic 5 rights (listed first) through upward of 11 rights of medication administration common in the literature (Frandsen & Pennington, 2021; McCuistion et al., 2021; Smeulers et al., 2015). Nurses should integrate reliance on embedded, sometime rote, processes with intentional decision-making grounded in clinical judgment.

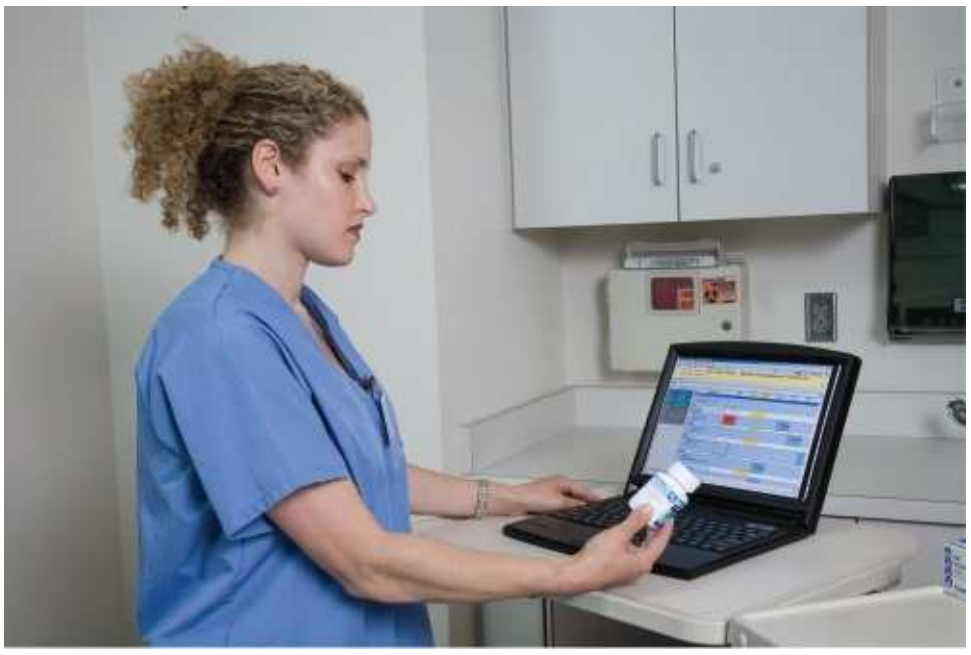

FIGURE 30-2. Comparing medication label with eMAR.

QSEN RIGHTS OF ADMINISTRATION

Keep in mind that nurses consider the rights of medication administration while adhering to standards of practice, policies, and procedures in order to promote safe medication administration.

Ensure that the (1) **right medication** is given to the (2) **right patient** in the (3) **right dosage** (in the right form) through the (4) **right route** at the (5) **right time** for the (6) **right reason** based on the (7) **right (appropriate) assessment data** using the (8) **right documentation** and monitoring for the (9) **right response** by the patient. Additional rights have been suggested to include (10) the **right to education**, ensuring that patients receive accurate and thorough information about the medication, and (11) the **right to refuse**, acknowledging that patients can and do refuse to take a medication. The first five rights are included in most references to the rights of medication administration and are the ones verified at each of the three checks. Validating the right reason requires the nurse to understand the rationale for administration and answer the questions, "Does it make sense?" and "Is it appropriate for this person?" The right documentation refers to accurate and timely documentation of administration. The right response refers to the evaluation by the nurse related to the effectiveness of the medication's intended purpose and monitoring the patient for the desired response. When a patient refuses to take a medication, the nurse should try to determine the reason for the refusal and take reasonable measures to convince the patient to take the medication, explaining the risk of refusal and reinforcing the reason for the medication. The patient's refusal and any education and/or explanation provided related to trying to facilitate administration must be documented. The primary care provider should be informed of the refusal, especially when the omission poses a specific threat to the patient (McCuistion et al., 2021).

In addition, it is important to acknowledge that nurses are not the only professionals responsible for the medication administration process. Medication administration is a process with many interconnected players, including clinical nurses, physicians, advanced practice professionals, pharmacists, and patients. All involved in the process share the responsibility for a safe medication system (Hanson & Haddad, 2020). Education and training should focus on

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

interprofessional roles and responsibilities, communication techniques, and other initiatives that foster the teamwork required to promote patient safety in medication administration processes (Bartlett & Kinsey, 2020).

Think back to **Mr. Baptiste**, the patient described in the beginning of the chapter and the Reflective Practice display. By adhering to the rights of medication administration, the nurse would be able to determine that the medication delivered by the pharmacy was labeled incorrectly.

Maintaining a Safe Environment

An environment that promotes safety and good working habits contributes to accuracy in the preparation of drugs for administration. Refer to the Research in Nursing display Practice Environments and Medication Errors on page 934. Nurses should be aware of the higher risk of making an error when their work flow is distracted or interrupted. Bravo, Cochran, and Barrett (2016) discuss physical working conditions that can influence the nurse's ability to perform safely, highlighting the need to decide whether to deflect, defer, or address distractions. An international study (Cottell et al., 2020) reported that participants identified the following as causes of medication incidents: (1) shortcoming in their individual knowledge, skills, and/or abilities; (2) patient and medication regimen complexities; (3) team factors related to communication, supervision, or support; (4) lack of clarity regarding policies, procedures, or protocols; and (5) the work environment including heavy workload, staffing mix, and availability of equipment. The hospital/unit structure, leadership, teamwork, communication, and required safety measures also impact on the environment, either positively or negatively affecting the probability of medication errors.

After beginning to prepare drugs for administration, do not leave them unattended. If it is imperative to leave for a short time, place the prepared drugs in a locked area, such as in the medication cart. The nurse who prepares the medication also administers the drug and records the drug administration. When not working at the medication dispensing system or medication cart, keep it locked. This is a requirement of the certifying bodies of hospitals.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Practice Environments and Medication Errors

Medication preparation and administration is primarily a nursing responsibility in the acute care setting. How do nurses cope when an error is made and how do they use this experience to prevent future errors?

Related Research

Athanasakis, E. (2019). A metasynthesis of how registered nurses make sense of their lived experiences of medication errors. *Journal of Clinical Nursing*, *28*(17–18), 3077–3095. https://doi.org/10.1111/jocn.14917

This meta-synthesis presents an analysis of published, sound qualitative studies that met defined inclusion criteria and focused on an exploration of nurses' lived experience with medication errors. Themes identified through this synthesis included: (1) human fallibility related to personal stress, workload, and distractions; (2) the emotional impact (ranged from self-doubt to shame, fear, and powerlessness) that resulted in symptoms often associated with post-traumatic stress disorder; (3) constructive learning that addressed individual as well as organizational accountability; (4) impact on licensure (registration in the United Kingdom) and employment; (5) copying strategies that stemmed from reassurance and support from trusted colleagues; (6) consideration of the patient status and safety; (7) root cause analysis; and (8) identification of preventative measures moving forward. Medication errors are a multifaceted issue with both positive and negative implications for nurses and the facilities where they work.

Relevance to Nursing Practice

Although the classification of a medication error can vary (error of omission through wrong dose/route/patient) and the associated ramifications for patients range from minor to severe, the impact of a medication error often extends past the immediate patient outcome. Nurses harbor feelings regarding the incident and must intentionally reflect on the lessons learned and clinical judgment processes, while also allowing themselves the space to grow and the grace

to continue in the profession.

Handling Controlled Substances Safely

Medication dispensing systems should be locked; this includes securement of controlled substances. Depending on the system used, controlled substances may be kept in an internal locked drawer or container as an added safety measure, providing for a *double locked* system. Opioids or other controlled substances may be prescribed only by physicians; in some states, nurse practitioners and physician assistants who are registered with the Department of Justice, Bureau of Narcotics, and Dangerous Drugs may prescribe them as well. According to federal law, a record must be kept for each narcotic that is administered. Although methods of recording may differ, the following information usually is required:

- Name of the patient receiving the controlled substance
- Amount of the substance used
- Hour the controlled substance was given
- Name of the prescribing provider
- Name of the nurse who administered the substance

It is a common practice to check controlled substances daily at specified intervals. In hospitals, this check is usually performed at each shift change. The number of doses of all controlled substances stored in the dispensing system is counted and must match the number of doses accounted for in the administration records. Many facilities use various computerized systems for dispensing narcotics and other controlled substances. Tracking controlled substances is often supported by the computerized automated dispensing cabinets that store unit dose medications for the unit. The nurse has a secure identification code that provides access to the system, identifies the patient by name or identification number, and prompts verification of the expected count of each drug as it is removed. Because the nurse's secure identification code is equivalent to the nurse's signature, it should never be given out to other staff members. Manual counting is warranted if a nurse discovers the controlled substance count is incorrect. A controlled substance count that does not match the count expected by the administration records must be reported and rectified immediately. The law requires these special precautions to aid in the control of substance use disorder by patients and health care workers.

The nurse administering controlled substances has an important responsibility to see that the federal law is observed. If for any reason a controlled substance prepared for administration has to be discarded, a second nurse should act as a witness. This validation by two nurses is recorded based on the requirements of the medication system in use. Document with a witness any time a full dosage is not given and some of the controlled substance needs to be discarded. For instance, if 3 mg of an opioid has been prescribed and the opioid is available in a vial of 4 mg/4 mL, the remaining 1 mg (1 mL) should be disposed of (also known as *wasted*) while a witness is watching, and both registered nurses should record the transaction according to facility policy and medication system in use.

FIGURE 30-3. Scanning the name-band as part of checking patient's identity. In addition to scanning, the patient should also verbally confirm two identifiers such as name and birthday (when possible).

Identifying the Patient

Positive identification of the patient is essential to safe drug administration. Before administering the drug, check carefully to see that the right drug is being given to the right patient. The 2020 National Patient Safety Goals established by The Joint Commission (2020a) states that whenever administering patient medications, at least two patient identifiers should be used. The patient's room number or physical location may not be used to validate patient identification. Patients in inpatient health care facilities usually wear identification bracelets, sometimes referred to as a *name-band* or *arm band*. Identify the patient by checking the identification wristband, as shown in Figure 30-3. Before referring to the patient by name, ask the patient (when possible) to verbally state their name and birthdate to verify they are wearing the correct arm band. Then validate the patient's name (first identifier) and identification number, medical record number,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and/or birth date (second identifier), comparing with the eMAR or MAR. Specific identifiers used depend on facility policy. If using a bar-code system, the nurse will also scan the patient's bracelet. Scanning, although an important safety step in the medication administration process, does *not* replace the need for verbal and visual confirmation of the patient's identity using two identifiers. The computer system will validate the patient's identification, but this does not replace the manual name-band and eMAR/MAR verification the nurse should perform. In some long-term care facilities, a current photograph of the resident, displayed above the resident's bed, can also be used for identification.

NURSING PROCESS FOR ADMINISTERING MEDICATIONS

Assessing

Assessment of the patient receiving medications begins during a nursing history. One component of this is the medication history, which informs the medication reconciliation process. During the interview, the nurse can adapt questions to meet the patient's needs and level of understanding. Avoid using medical jargon that the patient may not understand; use familiar terms as possible. For instance, the patient may refer to a diuretic as the "water pill" or to an anticoagulant as a "blood thinner." Areas to be included in the medication history are listed in the accompanying Focused Assessment Guide 30-1 on page 936.

The nurse caring for **Mildred Campbell** would need to incorporate the information the patient shared regarding her interest in an advertised medication when assessing the patient. This information is extremely important to prevent possible drug interactions should the patient decide to use the medication advertised on television.

Additional information to be assessed includes the patient's health status, current and past illnesses, laboratory test results, known drug allergies, and religious beliefs and/or cultural practices. Assess the patient with regard to medications during the nursing history and continue the assessment during and after medication administration.

Diagnosing Actual or Potential Health Problems and Needs

Data that the nurse collect may lead to diagnosing one or more actual or potential health problems or needs related to medication administration. Following diagnosing actual or potential health problems or needs, the nurse communicates their findings to other nursing and health care professionals through the use of the written and spoken word. The written health problem becomes a permanent part of the patient's health record. The actual and potential problems are verbally communicated during hand-off and interprofessional team meetings as part of the SBAR report. Examples of patient problems and needs with related etiology and signs and symptoms can be found in the box titled Examples of Actual or Potential Health Problems and Needs: Medication Administration on page 937.

Outcome Identification and Planning

Nursing measures for patients receiving medication are directed toward the patient's achievement of the following goals:

- Expected therapeutic effects will be demonstrated within a specified time frame
- Expected change in symptoms: for example, the patient's pain will be relieved, or vital signs will return to baseline
- Maintenance of therapeutic blood levels of medication
- The patient will correctly identify key information regarding prescribed medications

Implementing

Remain with the patient and make sure that the medication is taken. If the patient receives several drugs, offer them separately so that if one is refused or dropped, positive identification can be made, and the drug can be recorded or replaced. Open each medication package after providing any necessary teaching and confirming the patient will take the medication. Never leave medications at the bedside for the patient to take later. This is an unsafe practice because the patient may forget to take the medication, or someone else may take the medication. Record medication administration while or immediately after the patient takes the medication. Some facilities allow patients to self-administer certain drugs. Be familiar with facility policy on this matter.

Focused Assessment Guide 30-1

MEDICATIONS

Factors to Assess	Questions and Approaches
Previous and current drug use	• What medications are you taking that the primary care provider prescribed for you? • What over-the-counter medications and natural or herbal supplements are you taking on a regular basis? • Do you use nonmedicinal drugs (e.g., alcohol, caffeine, home remedies)? • How often do you use them? • What is the reason for taking the medications? • What medications have you taken during the past year and for what reasons? • Is there anything else you have tried to alleviate your symptoms?
Medication schedule	• At what times do you take your medications? • Is there a special way any of your medications has to be prepared (e.g., crushing and mixing with applesauce)? • Do you have any special method for remembering to take your medications?
Response to medications	• Do you have any allergies to medications? • Have the medications had the expected effects? • Have you ever experienced any adverse or unexpected reactions to the medications? • Is there a family history of this type of reaction to medications?
Attitude toward drugs and use of drugs	• How do you feel about taking medications? • Do you have any emotional responses regarding your medications (e.g. anxiety, distrust, fear, body image disturbance, anger, etc.) that may interfere with your desire to take the medications? • Why do you take the medications?
Adherence to regimen	• Can you tell me your understanding of the reason for taking the medications? • Can you describe how you follow the medication schedule? • Are there any problems that prevent you from following the medication regimen? • Can you afford your medications? • Do you have a reliable means for obtaining your medications (e.g. online delivery, pharmacy pick-up, transportation)? • Do you have adequate knowledge of how to take or administer your medications? • Have you performed a return demonstration for any complex administration procedures?
Storage	• Where are your medications stored at home? • How long do you keep medications in the home? • Can you show me any medications you have on hand?

Table 30-3 (on page 938) summarizes questions to ask and actions to take when administering drugs by any route to ensure the correct administration of medications, as well as examples of nursing interventions to promote safe medication administration and appropriate outcomes.

Administering Oral Medications

Drugs given orally are intended for absorption in the stomach and small intestine. The oral route is the most common route of administration. PO, the common shorthand for oral administration, is based on the Latin *per os*, which means "by mouth" (Frandsen & Pennington, 2021). It is usually the most convenient and comfortable route for the patient. Drugs administered orally have slower onset and a more prolonged, but less potent, effect than drugs administered via other routes. There are certain situations in which oral medications should not be administered, such as when the patient has difficulty swallowing, is unconscious, is to receive nothing by mouth (NPO), or is vomiting. Occasionally, a patient may unintentionally or intentionally hide a medication in the mouth. Ensure that the medication was actually swallowed before recording that it has been taken.

Oral medications are available in solid and liquid form. Solid preparations include tablets, capsules, and pills. Some tablets are scored (intentionally grooved by the manufacturer) for easy breaking if a partial quantity is needed. Unless a tablet is scored, do not break it by hand because doing so could result in an inaccurate dose. Enteric-coated tablets are covered with a hard surface that impedes absorption until the tablet has left the stomach; thus, the medication is released in the small intestine. Enteric-coated tablets are used when the active ingredient of the drug is irritating to the stomach mucosa. As a result, less gastrointestinal irritation occurs and the medication is protected from destruction by

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

gastric acid. Enteric-coated tablets should not be chewed or crushed because crushing the medication destroys the protective coating. Other forms of oral medications that should not be chewed or crushed without checking with the prescriber include any of the extended-release forms, such as SR (sustained release), ER (extended release), CR or CRT (controlled release), SA (sustained action), or LA (long acting). Chewing and/or crushing these medications destroys their extended-release delivery mechanism and may result in potentially toxic peaks and low troughs.

Examples of Actual or Potential Health Problems and Needs

MEDICATION ADMINISTRATION

Actual or Potential Health Problem or Need	Possible Etiologic Factors	Potential Signs and Symptoms
Knowledge Deficiency	• Introduction of new medication(s) • Varied drug interactions, side effects, adverse effects, and toxicities • Actual/potential person-centered implications related to class, action, administration, distribution, metabolism, or excretion of medication(s) • Complex directions regarding administration route and process	• Verbalizations of confusion • Anxiety regarding new medications • Inability to describe medication action, side effects, risk factors, or how to administer the medication
Risk for Alterations in Gastrointestinal Motility	• Eating habit change • Potential/actual drug interactions and absorption variations • Immobility • Stressors • Side effects associated with pharmaceutical agent and treatment regimen	—
Impaired Ability to Manage Medication Regime	• New medication regimen • Complex medication regimen • Lifestyle/role changes associated with medication regimen • Adherence issues involving social determinants of health such as access, affordability, and patient/caregiver engagement	• Inability to make choices of daily living that support medication regimen management • Failure to take medications as prescribed • Verbalization of difficulty in managing medication regimen • Manifestations of disease/disorder progression, lack of symptom management, and/or unintended signs and symptoms

Source: International Council of Nurses (ICN). (2019). *Nursing diagnosis and outcome statements*. https://www.icn.ch/sites/default/files/inline-files/ICNP2019-DC.pdf; Wolters Kluwer. (2022). Problem-based care plans. In Lippincott Advisor. Wolters Kluwer. https://advisor.lww.com/lna/home.do

Liquid preparations include elixirs, spirits, suspensions, and syrups. Some are water-based solutions, and others are alcohol-based solutions. If the patient has had a previous drug or alcohol addiction, it is important to carefully consider the administration of medications containing alcohol. Disposable, calibrated cups are available for the administration of liquid medications. For patients who find it difficult to take liquids from a cup, the medication can be placed in the mouth directly using a plastic, needleless, oral syringe. Place the syringe between the gum and cheek and give the liquid to the patient slowly—most adults can tolerate 5 mL at a time without issue. This technique, in addition to having the patient in an upright or side-lying position, helps prevent the patient from choking and aspirating the medication. Shake emulsions and suspensions well and administer them promptly to ensure an accurate

dosage.

Liquids are available in multidose bottles and single-dose containers. If a label becomes difficult to read or accidentally comes off the container, return the container to the pharmacy. Never give a medication from a bottle without a label or with a label that cannot be read with accuracy. Because of the danger of error and contamination, do not return unused medications to their bottles. Exercise care in pouring to prevent unnecessary loss. Do not transfer medications from one pharmacy container to another. Many medication bottles now have an identification code number on them. If similar medications were mixed and a patient had a reaction, it would be difficult to identify which drug was responsible. Do not use a medication with an unexpected precipitate, or one that has changed color. Skill 30-1 on pages 970–976 describes the techniques for preparing and administering oral medications.

SPECIAL TECHNIQUES

Certain drugs that are given orally can discolor the teeth or damage the enamel. The administration technique for this medication is to mix it well with water or some other liquid, have the patient take the medication mixed with liquid through a drinking straw, then encourage the patient to drink water after administration. This practice reduces the strength of the drug that comes in contact with the teeth.

Table 30-3 Ensuring Correct Administration of Medications

"RIGHT" TO ENSURE	QUESTIONS TO ASK	ACTIONS TO TAKE
When Preparing to Give Medication		
Right drug	• Has the patient been given this medication before? • Given the patient's symptoms and diagnosis, does it make sense for the patient to have this medication?	• Determine if the patient has any known drug allergies or sensitivities. • Assess the patient's other medications to detect possible contraindications. • Make sure it is the right medication; packaging, labeling, and spelling of some drugs look alike—watch for visual cues on packing or in how the drug name is written. • Have another person double-check medications and mathematical calculations (per policy).
Right reason	• Do the patient's condition, symptoms, and health status warrant receiving this medication?	• Determine if the patient has the condition the medication is used for and if rationale for the administration can be verified.
Right dose, route, and preparation	• Is the correct dose being administered? • How is the medication administered? • Does administration require medication math to calculate the dose?	• Ensure that labeling is legible and clearly understood. • Follow institution medication protocols as written.
Immediately before Administering the Medication		
Right patient	• Is this the right patient to receive this medication?	• Verify the identity of the patient using at least two identifiers: name and date of birth (check wristband, ask patient to state name).
Right time	• Is this the correct time for the medication to be administered?	• Check when the medication was last administered. If the drug is new, document when it is first given. Consider the facility's routine administration schedule.
Right route	• Is it appropriate to	• Check the original orders to verify the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	administer the medication orally, intravenously, by injection, or other route?	route of administration.
Right assessment data	• Is it appropriate to administer the medication, based on the specific data collected?	• Collect appropriate assessment data related to mechanism of action and/or therapeutic effect.
Right education	• Is the patient familiar with the medication? Does the patient understand the purpose, dosing, and administration information, as well as other information specific to medication?	• Assess patient's level of knowledge. Provide patient education as necessary. Consider the health literacy of the patient when teaching.
Right to refuse	• Has the patient verbally agreed to take the medication? Has the patient expressed any concern with the medication?	• Acknowledge the patient's right to self-determination. Provide education, then verify, document, and notify the provider about the refusal as needed.
After the Medication has been Administered		
Right documentation	• Has the correct documentation been completed according to facility policy?	• Complete documentation according to facility policy immediately after administering any medication. • Document and communicate to the appropriate health care provider any signs and symptoms indicative of any adverse effects.
Right response	• How is the patient responding to the medication?	• Monitor the patient to determine the efficacy of the drug, detect and prevent complication, and evaluate and document changes in health status. • When applicable, assess the patient's laboratory values to detect changes. • Provide patient education, when possible, so patient is alert to adverse effects and changes in how they feel.

Quality indicators for safe medication preparation and administration: A systematic review. *PLoS ONE*, *10*(4), e0122695. https://doi.org/10.1371/journal.pone.0122695.

Some patients object to the taste of certain medications. The following techniques help disguise or mask an objectionable taste:

- Crush the medication (if appropriate for type of medication) and mix with food or a drink so that the patient can swallow it. Many times the food or drink will mask the flavor of the medication. However, as previously discussed, some drugs cannot be crushed (e.g., enteric-coated and sustained-release capsules). Check with the pharmacist or a pharmacology reference if you are uncertain about crushing a medication.
- Allow the patient to suck on a small piece of ice for a few minutes before taking the medication. The ice numbs the taste buds, and the objectionable taste is less discernible.
- Store oily medications in the refrigerator. Cold oil is less aromatic than oil at room temperature.

- Place the medication in a syringe, and place the syringe on the back portion of the tongue (near the cheek), being careful not to trigger the patient's gag reflex. This places the medication on the part of the tongue with few taste buds.
- Offer oral hygiene immediately after giving the medication.
- Give the medication with generous amounts of water or other liquids, if permitted, to dilute the taste.

Children

It can be challenging to administer medications to infants and children. Children younger than 5 years have difficulty swallowing tablets and capsules. Therefore, most medications are available in liquid form. Nursing responsibilities includes teaching and preparing caregivers to administer medications to a child at home. In addition to understanding the medication prescription and the reason for the medication, the caregiver should be able to demonstrate any special techniques involved in administering the prescribed drugs. Question caregivers about their experiences giving medications to their children, about access to proper dosing devices, and previous use of the devices. Demonstrate how to use the appropriate dosing device that will be used at home. Ensure that the caregivers give a correct return demonstration. Help caregivers plan for the times of the day to give the medication. In addition, provide written instructions that clearly state the dose and times of the day for administration. Helpful strategies for administering oral medications to children include the following:

- Use a dropper to give infants or very young children liquid medications while holding them in a sitting or semi-sitting position. Place the medication between the gum and cheek to prevent aspiration.
- Crush uncoated tablets or empty a soft capsule (if appropriate for form of medication) and mix the medication with a bite of soft foods—such as potatoes, pudding, ice cream, or cooked or hot cereal—for children who are likely to aspirate liquids. However, as previously discussed, some drugs cannot be crushed (e.g., enteric-coated and sustained-release capsules). Check with the pharmacist or a pharmacology reference if you are uncertain about crushing a medication.
- Take care when selecting the food to be mixed with the medication. The item should not be an essential part of the child's diet, such as formula or the child's favorite food. The child may refuse to eat a food associated with medications.
- If a medication has an objectionable taste, warn the child if they are old enough to understand. Failing to warn the child is likely to decrease the child's trust in the nurse. Do not lie to a child about medication administration.
- Offer the child a flavored ice pop or frozen fruit bar immediately before taking the medication. It numbs the tongue, making the taste of the medication less evident.
- Praise the child for a job well done after the child swallows the medication.

Older Adults

Techniques for administering medications to older people include the following:

- Allow extra time to administer medications to older adults because their reflexes may be slowed and they may require additional explanation of the treatment regimen.
- Older adults may have difficulty swallowing medications and may find it easier to take their medications when crushed or given in liquid form. Initiate swallowing by gently massaging the laryngeal prominence or the area just below the chin prominence. The pressure from the gentle massage creates the desire to swallow. A speech therapist may offer additional suggestions for patients who have difficulty swallowing, such as a chin-to-chest position to increase the strength of the swallow.
- Reevaluation of the drug dosage is necessary with the older adult, especially when considering potential interactions and toxicities. Weight and age should be used as criteria for determining the dosage.
- Assist the older adult to set up a schedule as a reminder to take medications as scheduled at home. Associate medication with activities (such as breakfast or a television show) and not a specific time.
- Monitor the patient carefully for adverse effects that may result from the drug regimen. Encourage the patient to have all prescriptions filled at one pharmacy to facilitate appropriate management of the patient's entire medication regimen.
- Teach patients the names of drugs, rather than distinguishing them by color. Manufacturers may vary the colors of generic drugs, and the visual changes associated with aging may make it more difficult to identify medications by their color.
- Empower patients to take control of their health by providing education and ongoing support focused on adherence to the medication regimen.

Technology Alert

Remote Medication Monitoring System

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Telehealth is an emerging technology that allows for remote communication between a patient and the provider. Remote monitoring of vital signs, weight, and patient-reported symptoms frequently occurs with telehealth monitoring. Hale et al. (2016) describe a specific remote medication monitoring system piloted with older adults diagnosed with heart failure, a complex disease process that requires diligent ongoing medication and symptom management. The technology used includes (1) a device (outfitted with daily dispensing bins, sensors for each bin, and a camera) that alerts the patient with lights and sounds when medications are due; and (2) a monitoring center staffed by advisors who provide reminders to refill the system each week and follow-up calls to the patient and an appointed caregiver when medications are not taken. Although the results are mixed and more studies need to be done, this type of relatively low-cost technology shows promise in supporting patients with medication adherence.

ADMINISTERING MEDICATIONS THROUGH AN ENTERAL FEEDING TUBE

Patients with a gastrointestinal tube (nasogastric, nasointestinal, percutaneous endoscopic gastrostomy [PEG], or jejunostomy [J] tube) often receive medication through the tube. The insertion of the tube and care of the patient with an enteral feeding tube are described in Chapter 37. Current recommendations support the use of enteral feeding connections that comply with the International Organization for Standardization (ISO) 80369-1 or ISO 80369-3 standard (FDA, 2018b). These connectors, such as ENFit® , are designed to provide secure and unique (different from intravenous) adaptors and connections specifically designed for enteral feeding systems. Suggestions for preparing and administering medications through the tube have been fairly consistent for the past 10 to 15 years:

- Verify the current feeding tube's placement (distal location) and patency—note that tubes that terminate in the stomach can tolerate larger boluses than tubes that sit in the intestines (Reber et al., 2019).
- Verify the dosage form, drug, formulation, and any preparation steps with the prescription/order (Boullata et al., 2017).
- Use liquid medications if they are appropriate for enteral administration. In liquid medication not specifically formulated for enteral administration, sugars, preservatives, and agents that thicken the solution may cause gastrointestinal disturbances and impact on medication absorption (Bandy et al., 2019; Boullata et al., 2017; Zoeller et al., 2020). Dilute thick suspensions as needed, typically with equal parts medication and (purified) water (Boullata et al., 2017).
- Certain immediate-release solid dosage medications can be crushed and made into a slurry. Grind medication to a fine powder and mix it with 30 mL of (purified) water immediately before administration through the tube (Bandy et al., 2019; Boullata et al., 2017; Zoeller et al., 2020).
- Certain capsules may be opened, the powder emptied into (purified) water, and the medication administered through the tube. Check manufacturer recommendations and/or with a pharmacist to verify (Boullata et al., 2017).
- Attach a clean oral/enteral syringe (≥20 mL) for administering flushes and medication(s) (Boullata et al., 2017).
- Flush the tube with at least 15 mL (purified)water (at least 5 mL for children) before giving each medication and immediately after giving each medication (Boullata et al., 2017; Zoeller et al., 2020). Flushing helps to maintain tube patency.
- Give medications separately and flush with water between each drug (Boullata et al., 2017). The medications may not be physically or chemically compatible—mixing them can lead to tube obstruction or altered therapeutic actions (Boullata et al., 2017).
- Although the research is not conclusive, if a medication needs to be administered down a nasogastric tube connected to suction, keep it disconnected from the suction and clamped for 30 minutes after administration of the medication to allow absorption (Bandy et al., 2019).
- If the patient is receiving tube feedings, review information about the drugs to be administered. Absorption of some drugs is affected by tube-feeding formulas. Discontinue a continuous tube feeding and leave the tube clamped for the required period of time before and after the medication has been given, according to the reference and facility protocol.
- Document the total water and liquid medication volume on the intake and output record. Adjust the amount of water used if the patient's fluid intake is restricted. Always follow institution policy and procedure regarding administering medications through an enteral feeding tube (Boullata et al., 2017).
- Keep in mind the importance of interprofessional collaboration between the prescribing provider, the pharmacist, and the nurse to ensure safe enteral medication prescribing, preparation, and administration (Bandy et al., 2019; Boullata et al., 2017; Reber et al., 2019).

Concept Mastery Alert

When administering medications via an enteral tube, the same amount of purified water—at least 30 mL—is used to mix the medication and to flush the tube (15 mL before and 15 mL after medication administration).

ADMINISTERING SUBLINGUAL AND BUCCAL MEDICATIONS

Certain drugs, such as nitroglycerin, are administered sublingually. This means a tablet is placed under the patient's tongue. Another method is to administer the medication between the cheek and gum, known as buccal administration. These areas are rich in superficial blood vessels, which allow the drug to be absorbed relatively rapidly into the bloodstream for quick systemic effects. Sublingual and buccal medications should not be swallowed, but rather held in place so that complete absorption can occur. Before administering a sublingual or buccal drug, offer the patient a drink of water (if the patient is permitted to have fluids) or oral care (if the patient is NPO). This ensures that the tablet will dissolve appropriately. Certain opioids that were previously available for parenteral administration only can now also be administered in a lollipop or oral-transmucosal form.

Administering Parenteral Medications

The word **parenteral** means outside the intestines or alimentary canal. Several methods to administer a medication by the parenteral route involve injecting the medication into those body tissues outside of the intestines or alimentary canal and into the circulatory system. Table 30-2 on page 928 defines terms used to describe various types of parenteral injections. Advanced injection techniques consist of injecting medications into an artery, the peritoneum, heart tissues, the spinal canal, and bones. Intraosseous administration continues to be supported by the American Heart Association (2020) and certifications they support include this training. Techniques for injecting medications into all of these areas are discussed in advanced clinical texts. In most instances, physicians, advanced practitioners, or specially trained providers are responsible for these procedures.

EQUIPMENT

Needles and Syringes

Needles are available in various lengths and gauges, with different sizes of bevels. The needle length used depends on the route of administration. The gauge refers to the diameter of the needle. Needle gauges are numbered 18 through 30. As the diameter of the needle increases, the gauge number decreases. For example, an 18-gauge needle is larger in diameter than a 30-gauge needle. The bevel of the needle is its sloped edge, designed to make a narrow, slit-like opening that closes quickly.

Concept Mastery Alert

Opposites rule. The larger the gauge of a needle, the smaller the diameter.

Syringes are supplied in various sizes. Most syringes are plastic and disposable. Some syringes are supplied with the needle attached; others are not, in which case you should select an appropriate needle. Figure 30-4 shows the parts of a needle and the parts of a syringe.

Choose the equipment needed for an injection based on the following criteria:

- *Route of administration:* A longer needle is required for an intramuscular injection than for an intradermal or a subcutaneous injection. See the discussion related to each individual route for specific guidelines regarding needle length and gauge.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

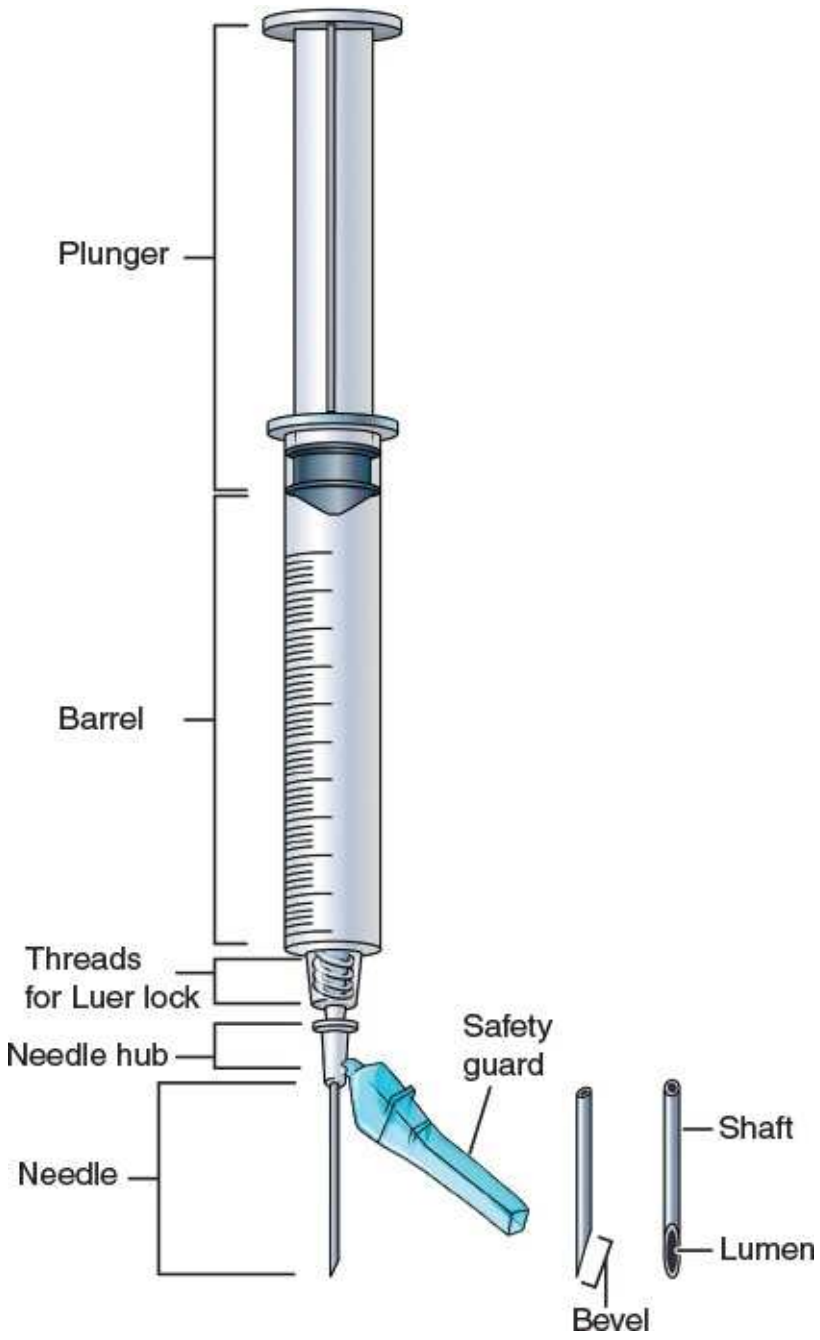

FIGURE 30-4. Parts of a needle and syringe.

- *Viscosity of the solution:* Some medications are more viscous (thick) than others and require a needle with a large lumen to inject the drug.
- *Quantity to be administered:* The larger the amount of medication to be injected, the larger the syringe needs to be. Smaller syringes should be used as needed for precise dosing because they provide smaller increments of measurement—never estimate a dose. For example, a 1-mL syringe provides increments of 0.01 mL, but a 5-mL syringe allows for precise measures only down to 0.2 mL.
- *Body size:* An obese person requires a longer needle to reach muscle tissue than does a thin person. A thin person or an older adult with decreased muscle mass requires a shorter needle.
- *Type of medication:* There are special syringes for certain uses. An example is the insulin syringe used only to inject insulin.

Once used on a patient, do not recap needles. After use, activate the safety device to cover the tip of the needle and place the needle with the syringe attached in an approved puncture-resistant container. Because most needlesticks are related to unsafe needle devices, and not unsafe or careless behavior by healthcare workers, health care facilities are required by the Occupational Safety and Health Administration (OSHA) Needlestick Safety and Prevention Act of 2001 to provide needles with built-in or add-on safety control devices to prevent accidental injury (OSHA, 2012). Some examples of built-in safety device designs include needleless connector systems, self (re-)sheathing for syringes and scalpels, retractable needles or lancets, or self-blunting technology. Some needle and syringe combinations have a retractable needle that locks and seals inside the syringe barrel. Prefilled syringes are manufactured with retractable needle sheath covers. With these syringes, once the needle is contaminated, the top slides forward and over the needle to prevent a needlestick injury. Add-on safety features are common in the clinical setting and include a hinged needle guard safety feature. After the injection is given, push the needle guard into place using the one-handed technique recommended by manufacturers to prevent injury (OSHA, n.d.).

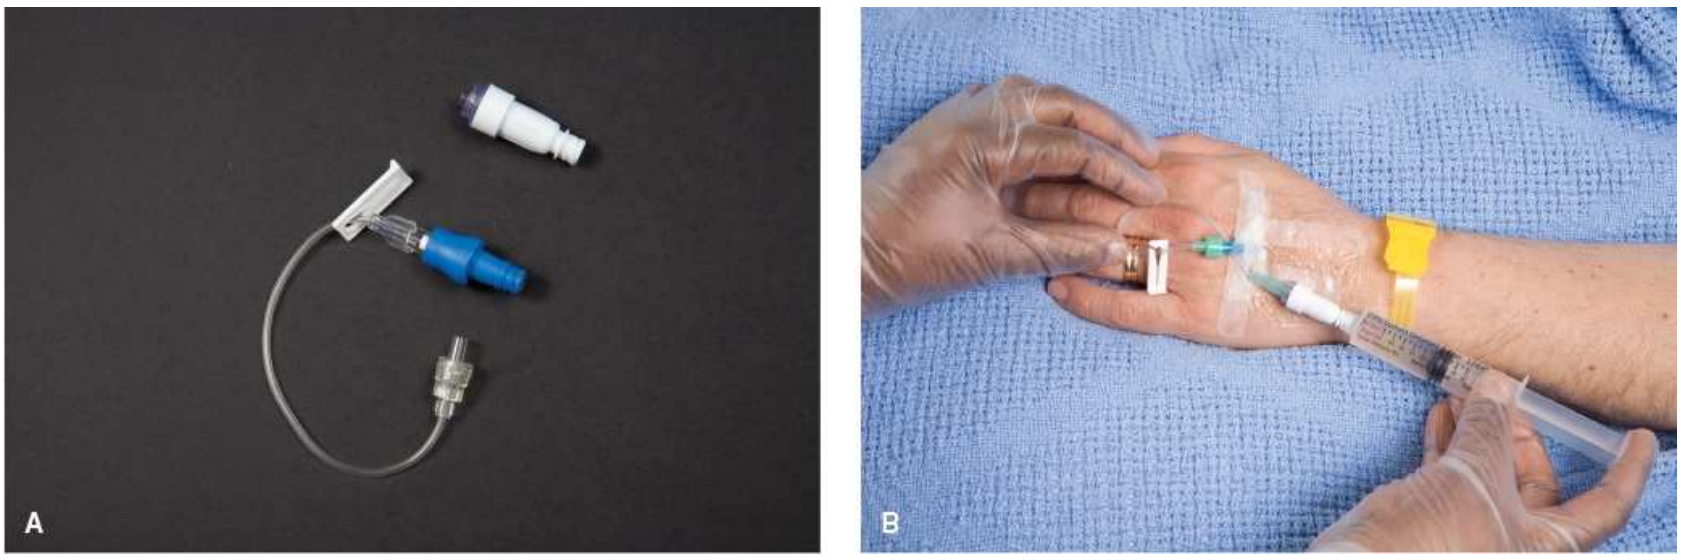

FIGURE 30-5. A. Needleless administration devices. **B.** Syringe attached to needleless administration device. (*Source:* Used with permission from Shutterstock. *Photos by B. Proud.)*

When administering parenteral injections, maintain surgical asepsis and use strict sterile technique to avoid introducing organisms into the body. The parts of the syringe and needle that must be kept sterile during the procedure of preparing and administering an injection include the inside of the barrel, the part of the plunger that enters the barrel, the tip of the barrel (threads for Luer lock), and the needle, except for the exterior of the needle hub. Never open and set down a syringe or needle. To maintain sterility, first open the syringe (being careful not to handle the tip of the barrel) and then open the needle (or needleless adapter) from the hub side, screwing the needle onto the syringe threads while the covered tip of the needle is still in the package. Surgical asepsis also applies to cleaning the skin for an injection. Cleanse the skin with alcohol in a circular motion, working from the center of the designated site outward. Follow manufacturer recommendations when preparing the site using other antimicrobials (e.g., back and forth motion with chlorhexidine products).

Needleless Systems

The risk for accidental needlesticks and exposure to blood-borne pathogens is reduced significantly with the use of needleless devices or protected needles. Chapter 25 describes the rationale for these systems of protection for health care workers. Needleless systems are available for intravenous use, including recessed and shielded intravenous needle connectors, as well as blunt cannulas that are inserted into special receptor sites on tubing or lock setups. Discard all needleless devices or blunt cannulas in special containers that are puncture-proof, leak-proof, and labeled clearly. Figure 30-5 shows an example of a needleless administration device.

PREPARING MEDICATIONS FOR ADMINISTRATION BY INJECTION

Drugs that are administered by injection are packaged in several ways. Those that deteriorate in solution are usually dispensed as powders and are reconstituted immediately before injection. Drugs that remain stable in solution are usually dispensed in ampules, bottles, prefilled cartridges, or vials in an aqueous or oily solution or suspension. Drugs may be dispensed in single-dose glass ampules, single-dose rubber-capped vials, multidose rubber-capped vials, and prefilled cartridges.

Removing Medication From an Ampule

An **ampule** is a glass flask that contains a single dose of medication for parenteral administration. Figure 30-6 shows an example of an ampule. There is no way to prevent airborne contamination of any unused portion of medication after the ampule is opened; if not all the medication is used, discard the remainder. Medication is removed from an ampule after its thin neck is broken. Take special care when breaking the ampule so that you do not get cut. If you cut yourself on the ampule, discard the ampule and medication. Because of the risk of small glass shards falling into the ampule, use a filter needle to remove the medication from the vial and then discard it appropriately. Invert the ampule or place it on a flat surface to draw the solution into the syringe. Care must be taken not to contaminate the needle by touching the rim of the ampule. Replace the filter needle with an unfiltered needle of appropriate size on the syringe before administering the medication. Skill 30-2 on pages 976–979 shows how to remove medication from an ampule.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 30-6. Ampule. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

Removing Medication from a Vial

A **vial** is a plastic or glass bottle with a self-sealing stopper through which the medication is removed (Fig. 30-7). For safety in transporting and storing, the vial is usually covered with a soft metal or plastic cap that can be removed easily. The self-sealing rubber stopper under the removed cap is the means of entrance into the vial.

Some drugs are dispensed in vials that contain several doses. This means that the nurse can remove several doses from the same container. To prevent microbial growth in the vial, each multidose vial is usually good for only 24 hours. Label the vial with the time and date when first used. To facilitate removal of medication from a multiuse vial, inject air into the vial; single-use vials often do not require instillation of air. The amount of air injected into the vial is the same amount as the desired quantity of solution. The Centers for Disease Control and Prevention (CDC, 2015) recommends that medications packaged as multiuse vials be assigned to a single patient whenever possible. In addition, it is recommended that the top of the vial be cleaned prior to each entry and that a new sterile needle and syringe is used with each entry. Skill 30-3 on pages 980–982 details how to remove medication from a vial.

Using a Prefilled Cartridge or Syringe

Prefilled cartridges provide a single dose of medication. Insert the cartridge into a reusable holder or injection device. Before giving the injection, check the dosage in the cartridge and clear the cartridge of excess air. Most prefilled cartridges are overfilled; therefore, eject any excess medication to give an exact dose and avoid a medication error. Tubex and Carpuject are two types of prefilled cartridges. Figure 30-8 shows examples of prefilled cartridges and injector devices. Integration of safety principles associated with these devices requires nurse and leadership engagement, adequate education, and policies and procedures to guide practice (Prentiss et al., 2016). Prefilled cartridges should not be used as vials in routine practice (Institute for Safe Medication Practices, 2018).

FIGURE 30-7. Vials. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

FIGURE 30-8. Prefilled cartridge and injector device. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

Similar to prefilled cartridges are prefilled syringes. These are syringes that are already filled with a medication and usually have their own needle attached. Like prefilled cartridges, these syringes also come with excess air. In some cases, this air should *not* be expelled before administering the medication. Enoxaparin is an example of a syringe for which the air should not be expelled before administering (Sanofi-Aventis, 2020).

Mixing Medications in One Syringe

When considering mixing two medications in one syringe, first ensure that the two drugs are compatible. Certain medications, such as diazepam, are incompatible with other drugs in the same syringe. Other drugs have limited compatibility and should be administered within 15 minutes of preparation. Incompatible drugs may become cloudy or form a precipitate in the syringe. Discard these medications and re-prepare the drugs in separate syringes. Mixing more than two drugs in one syringe is not recommended. If it must be done, contact the pharmacist to determine the compatibility of the three drugs, as well as the compatibility of their pH values and the preservatives that may be present in each drug. A drug compatibility table should be available to nurses who are preparing medications.

Preparation of medications in one syringe depends on how the medication is supplied. When using a single-dose vial and a multidose vial, inject air into the multidose vial and draw the medication in the multidose vial into the syringe first. This prevents the contents of the multidose vial from being contaminated with the medication in the single-dose vial. The steps to follow when preparing medications from two multidose vials in one syringe are illustrated in Figure 30-9. When preparing medications from an ampule and a vial, prepare the medication in the vial first. Draw up the medication in the ampule after the medication in the vial.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

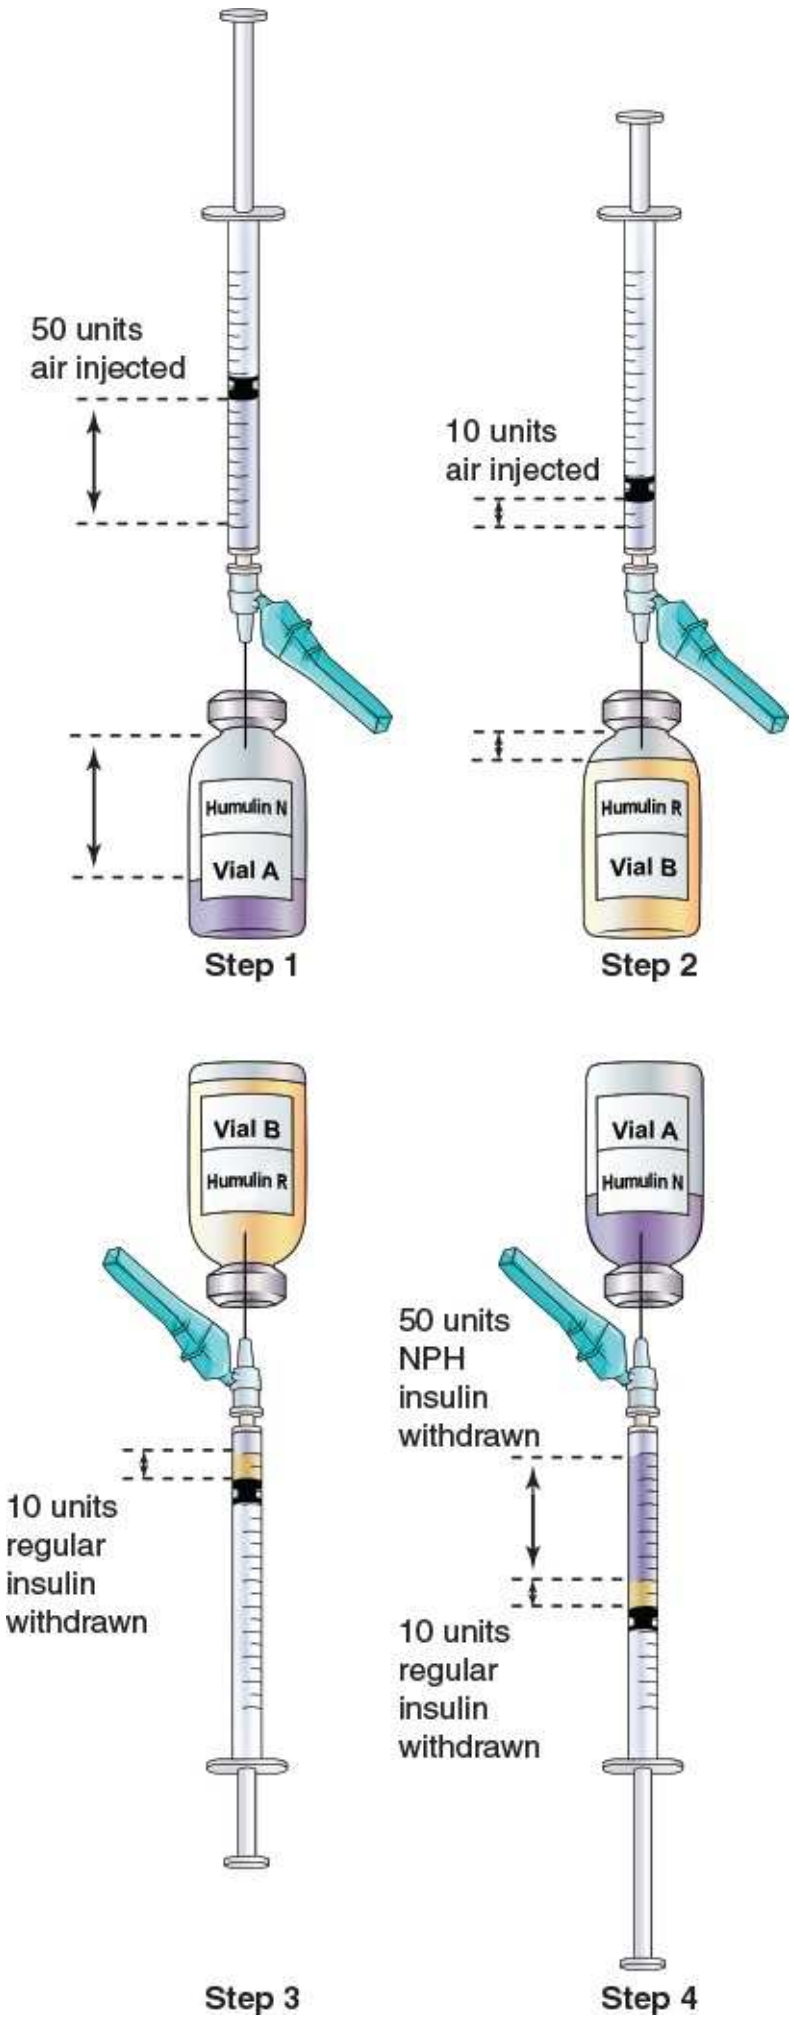

FIGURE 30-9. Mixing medications (insulin) in one syringe.

Mixing Insulins in One Syringe

Insulin, a naturally occurring hormone produced by the pancreas, enables cells to use carbohydrates. Two of the issues relative to insulin in patients with diabetes mellitus include no insulin production or insufficient insulin production. Many types of insulin are available for use by patients with diabetes mellitus. Insulins vary in their onset and duration of action and are classified as rapid acting, short acting, intermediate acting, and long acting (Frandsen & Pennington, 2021). A patient may receive more than one type of insulin. A patient may be treated with a basal insulin, such as insulin glargine, insulin detemir, or NPH insulin to cover the body's basal metabolic needs. In addition, the patient will probably also be treated with a prandial (with a meal) or preprandial (before a meal) insulin, such as insulin lispro or insulin aspart, to prevent postprandial (after meal) hyperglycemia (high blood glucose). Glargine and detemir cannot be mixed with other insulins. Patients treated with other insulins may require the mixing of the two insulins in one syringe. Before administering any insulin, be aware of the onset time, peak, and duration of effects and ensure that proper food is available. Refer to a drug reference for a listing of the different types of insulin and action specific to each type.

Insulin is typically available in multidose vials, and dosages are calculated in units. The scale commonly used is

U100, which is based on 100 units of insulin contained in 1 mL of solution. An insulin syringe is also calibrated in units. Insulin is also available in injection pens. Before administering insulin, check the dosage with the prescription. Skill 30-4 on pages 983–986 gives the steps for mixing two types of insulin in the same syringe. Insulin administration is discussed below in the Administering Medications Subcutaneously section.

Reconstituting Powdered Medications

Occasionally, a drug is supplied as a powder in a vial. A liquid, or diluent, must be added to the powder before it is administered as a solution. The technique of adding a diluent to a powdered drug is called *reconstitution*. Information needed for reconstitution, such as the specific solution to use for the diluent and dosage calculation, is usually found on the vial label or a package insert. Additional sources of information about reconstitution of medications are the pharmacist and electronic resources, such as a medication database.

Another form that powdered medications may come in is an Act-O-Vial (Pfizer). Act-O-Vials have the diluent and powder in the same vial but separated by a rubber stopper. When the nurse is ready to administer the medication, the rubber stopper is deployed, and the Act-O-Vial is agitated gently to mix the diluent and powder.

ADMINISTERING MEDICATIONS INTRADERMALLY

Intradermal injections are administered into the dermis, just below the epidermis. The intradermal route has the longest absorption time of all the parenteral routes. For this reason, intradermal injections are used for sensitivity tests, such as tuberculin and allergy tests, and local anesthesia. The advantage of the intradermal route for these tests is that the body's reaction to substances is easily visible, and degrees of reaction are discernible by comparative study.

Sites commonly used are the inner surface of the forearm, the upper chest, and the upper back, under the scapula. Equipment used for an intradermal injection includes a tuberculin syringe calibrated in tenths and hundredths of a milliliter. A ⅜″ to ½″, 26- or 27-gauge needle is typically available. The dosage given intradermally is small, usually less than 0.5 mL. The angle of administration for an intradermal injection is 5 to 15 degrees. Skill 30-5 on pages 987–991 demonstrates how to administer an intradermal injection.

ADMINISTERING MEDICATIONS SUBCUTANEOUSLY

Subcutaneous injections are administered into the adipose tissue layer just below the epidermis and dermis. This tissue has few blood vessels, thus drugs administered here have a slow, sustained rate of absorption into the capillaries. This route is used to administer drugs such as insulin and heparin.

Subcutaneous Injection Sites

Various sites may be used for subcutaneous injections, including the outer aspect of the upper arm, the abdomen (from below the costal margin to the iliac crests), the anterior aspects of the thigh, the upper back, and the upper ventral or dorsogluteal area (Fig. 30-10). In general, avoid sites that are bruised, tender, hard, swollen, inflamed, or scarred. Absorption rates differ among the various sites. Injections in the abdomen are absorbed most rapidly; ones in the arms are absorbed somewhat more slowly; those in the thighs, even more slowly; and those in the upper ventral or dorsogluteal areas have the slowest absorption (American Diabetes Association [ADA], 2022).

Equipment

It is important to choose the right equipment to ensure depositing the medication into the intended tissue layer and not the underlying muscle. Equipment used for a subcutaneous injection includes a syringe of appropriate volume for the amount of drug being administered. A 25- to 30-gauge, ⅜″ to 1″ needle can be used. The 25-gauge ⅝″ needles are most commonly used for adults. Needle length ranges exist because patients present with different amounts of subcutaneous tissue that varies based on age, body mass index, sex, and general build—choose the needle length that ensures the needle terminates in the subcutaneous tissue. Usually, no more than 1 mL of solution is given subcutaneously. Giving larger amounts adds to the patient's discomfort and may predispose to poor absorption. Some medications are packaged in prefilled cartridges with a needle attached. Enoxaparin, for example, is provided this way. Confirm that the provided needle is appropriate for the patient before use.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

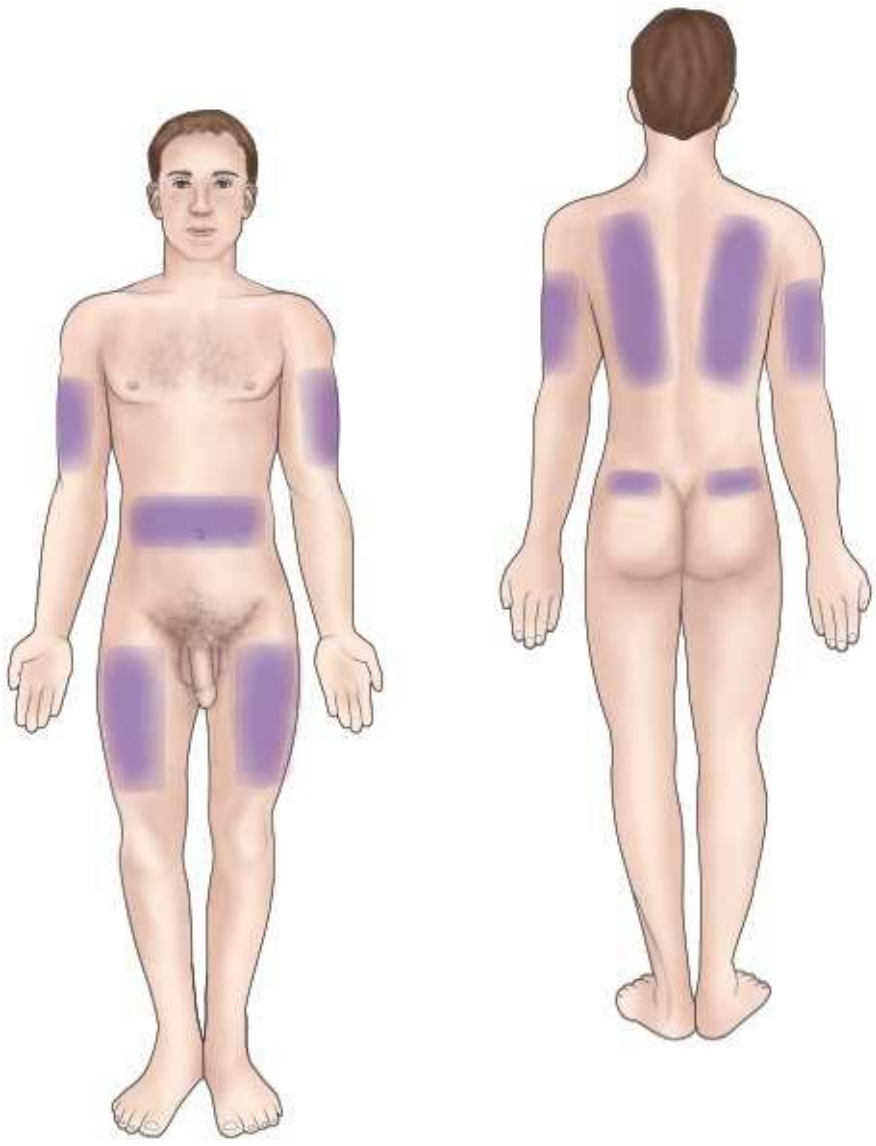

FIGURE 30-10. Sites on the body where subcutaneous injections can be given.

Procedure

Subcutaneous injections are administered at a 45- to 90-degree angle, with the 45-degree angle used only for small patients with a limited amount of subcutaneous tissue. Choose the angle of needle insertion based on the amount of subcutaneous tissue present and the length of the needle. In general, the shorter, ⅜″ needle should be inserted at a 90-degree angle (common on prefilled and insulin syringes), and the longer, ⅜″ needle may be inserted at a 45-degree angle. Recommendations differ regarding pinching or bunching of a skin fold for administration (Centers for Disease Control and Prevention, 2015/2020). Pinching is advised for thinner patients and when a longer needle is used to lift the adipose tissue away from underlying muscle and tissue. If pinching is used, once the needle is inserted, release the skin and stabilize the base of the needle to avoid injecting into compressed tissue.

If blood or clear fluid appears at the site after withdrawing the needle, apply gentle pressure. Massaging the site is not necessary and can damage underlying tissue as well as increase the absorption of the medication. Massaging after heparin administration can contribute to hematoma formation.

It is necessary to rotate sites or areas for injection if the patient is to receive frequent injections. This helps to prevent buildup of fibrous/adipose tissue and permits complete absorption of the medication. Because absorption rates vary from site to site, it is recommended that patients administering their own insulin use the same area of the body at the same time every day to ensure more consistent absorption and prevent tissue changes from repeated use of the same site (American Diabetic Association, 2022; Frandsen & Pennington, 2021; Karch, 2020). For instance, every morning the patient may use the abdomen for insulin injection, and every evening before dinner, the patient may inject the insulin into the arms or thighs. Keep in mind that the best absorption occurs in the abdomen. In each case, the injections should be given an inch away from the previous injection site. A small spot bandage or piece of tape can be used to mark the first injection site, with subsequent injections rotated in a circle around that site. After this area has been used, an adjacent site, an inch away, can be selected, using the same rotation format. A marked diagram incorporated into the patient's plan of care is also helpful for noting alternative sites. Do not rely on memory. The patient cannot always recall the site of the previous injection; therefore, the site of administration must be recorded in the patient's record.

Box 30-2 **Reducing Discomfort in Subcutaneous and Intramuscular Administrations**

The following are recommended techniques for reducing discomfort when injecting medications subcutaneously or intramuscularly:

- BeSelect a needle of the smallest gauge that is appropriate for the site and solution to be injected, and

select the correct needle length.
- Be sure the needle is free of medication that may irritate superficial tissues as the needle is inserted. The recommended procedure is to use two needles—one to remove the medication from the vial or ampule and a second one to inject the medication. If medication is in a prefilled syringe with a nonremovable needle and has dripped back on the needle during preparation, gently tap the barrel to remove the excess solution.
- Use the Z-track technique for intramuscular injections to prevent leakage of medication into the needle track, thus minimizing discomfort.
- Inject the medication into relaxed muscles. There is more pressure and discomfort when the medication is injected into a contracted muscle.
- Do not inject areas that feel hard on palpation or tender to the patient.
- Insert the needle with a dart-like motion without hesitation, and remove it quickly at the same angle at which it was inserted. These techniques reduce discomfort and tissue irritation.
- Do not administer more solution in one injection than is recommended for the site. Injecting more solution creates excess pressure in the area and increases discomfort.
- Inject the solution slowly so that it may be dispersed more easily into the surrounding tissue (10 seconds per 1 mL).
- Apply gentle pressure after injection, unless this technique is contraindicated.
- Allow patients who are fearful of injections to talk about their fears. Answer patients' questions truthfully, and explain the nature and purpose of the injection. Taking the time to offer support often allays fears and decreases discomfort.
- Rotate sites when the patient is to receive repeated injections. Injections in the same site may cause undue discomfort, irritation, or abscesses in tissues.
- For children, provide age-appropriate support and involve their parent, guardian, or other support person when possible.

Skill 30-6 on pages 991–996 shows the procedure for administering medications subcutaneously. Techniques for reducing discomfort in subcutaneous administrations are listed in Box 30-2.

Drug-Specific Equipment and Techniques

Various drugs require very specific equipment and/or techniques. Insulin is prepared using an insulin syringe. Other drugs are never administered with an insulin syringe. Insulin syringes are available with 28- to 31-gauge, $^{5}/_{16}$″ and ½″ length needles, and in 3/10-mL to 1-mL sizes. The shorter needles ($^{5}/_{16}$″) are the most common length used. Shorter needles cause less pain, and there is less risk for inadvertent injection into muscle tissue. Insulin pens are also available for insulin administration. Insulin injection pens are prefilled devices that combine the insulin container and syringe. Patients attach a needle for each administration, dial a dose of insulin, and depress a plunger to administer the dose. See Guidelines for Nursing Care 30-1: Using an Insulin Injection Pen.

Heparin is also administered subcutaneously. The abdomen is the most commonly used site. Avoid the area 2″ around the umbilicus and the belt line. Certain medications have specific manufacturer-recommended administration requirements. For example, low–molecular-weight heparin (enoxaparin) should be administered in the alternating "left and right anterolateral and left and right posterolateral abdominal wall[s]" (Sanofi-Aventis, 2020, section 2.5 Administration; Fig. 30-11). To administer the medication, pinch the tissue gently and insert the needle at a 90-degree angle. In addition, enoxaparin is packaged in a prefilled syringe with an air bubble. Do not expel the air bubble before administration. A Cochrane review considered data from four randomized control trials regarding the effects of speed of administration of heparin and low molecular weight heparin (enoxaparin) on pain, bruising, and hematoma formation. The evidence shows that there is essentially no difference in the patient experience whether the injection is administered slowly (over 30 seconds) or quickly (over 10 seconds). Although the pain associated with slow injection may have been less 48 hours after the heparin injection (low evidence), there was no clear difference in pain immediately or 60 to 72 hours after the injection (Mohammady et al., 2017; Pich, 2020). At the individual level, nurses need to use evidence and research to support their clinical judgment and engage in evidence-informed practice. At the systems level, nurses need to bring these studies forward because they impact on the policies and procedures at their individual institutions.

Some medications, such as insulin and morphine, may be administered continuously via the subcutaneous route. Continuous subcutaneous insulin infusion (CSII or insulin pump) allows for multiple preset rates of insulin delivery. This system uses a small computerized reservoir that delivers insulin via tubing through a small plastic cannula or needle inserted into the subcutaneous tissue. The pump is programmed to deliver a continuous dose of insulin (basal) and allows for the administration of on-demand (bolus) administration as needed for meals or an elevation in blood glucose. The settings may be adjusted as needed for things such as exercise and illness. This type of insulin administration more closely mirrors the body's normal function and promotes better blood glucose control, increases

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

quality of life, and reduces potential microvascular and macrovascular complications of diabetes (Nimri et al., 2020). Sites are changed every 2 to 3 days according to the manufacturer's recommendations. Figure 30-12 (on page 948) shows a patient wearing an insulin pump. Another example of a medication given via continuous subcutaneous infusion is morphine. Subcutaneous morphine infusion can be used for palliative dyspnea and pain management. Advantages of continuous subcutaneous medication infusion include the sustained rate of absorption via the subcutaneous route and convenience for the patient.

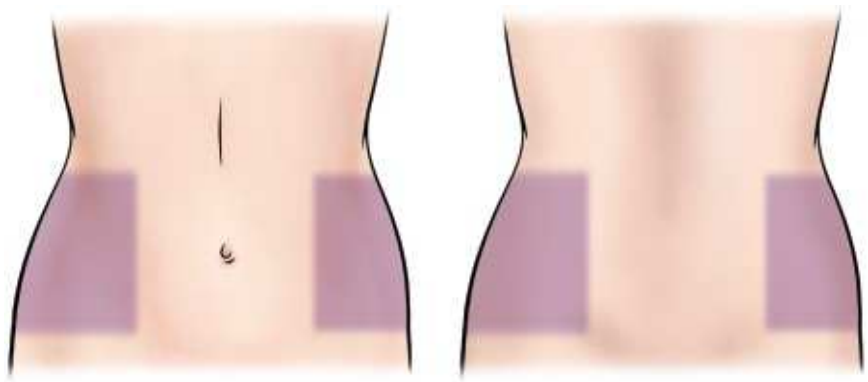

FIGURE 30-11. Sites for administration of enoxaparin.

Guidelines for Nursing Care 30-1

Using An Insulin Injection Pen

- Perform hand hygiene and put on PPE, as indicated.

- **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two methods** (The Joint Commission, 2020a).
- Explain procedure to the patient.
- Close the door to the room or pull the bedside curtain.
- **Complete necessary assessments before administering medications. Check the patient's allergy bracelet or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**
- Scan the patient's bar code on the identification band, if required.
- **Based on facility policy, the third check of the label may occur at this point. If so, recheck the labels with the eMAR/MAR before administering the medications to the patient.**
- Select an appropriate administration site.
- Assist the patient to the appropriate position for the site chosen. Drape, as needed, to expose only area of site to be used.
- Identify the appropriate landmarks for the site chosen.
- Remove the pen cap.
- Insert an insulin cartridge into the pen, if necessary, following the manufacturer's directions.
- If administering an insulin suspension, gently roll the pen 10 times and invert the pen 10 times to mix the insulin.
- Scrub the self-sealing seal end of the pen cartridge holder with an antimicrobial swab.
- Remove the protective paper tab from the needle.
- Screw the needle onto the reservoir. (Patients at home should reserve the outer shield for later use.) Dial the dose selector to 2 units to prime the pen (perform an *air shot*) to get rid of air and make certain the pen is working properly.
- Hold the pen upright and tap to force any air bubbles to the top.
- Hold the pen upright and press the injection button or plunger firmly. Watch for a drop of insulin at the needle tip.
- Check the drug reservoir to make sure enough insulin is available for the dose.
- Check that the dose selector is at 0 (zero), then dial the units of insulin for the dose.
- Put on gloves.
- Clean the injection site. If the pen needle is longer than 5 mm, gently pinch the skin at the injection site to form a skin fold (Becton, Dickinson and Company [BD], 2020).

- Hold the pen in the palm of your hand, perpendicular to the forearm, with your thumb at the injection button end of the pen. Use your thumb for injection.
- Administer the subcutaneous injection. Press the injection button on the pen all the way in. Keep the button depressed and count to 10 before removing from the skin.
- The safety shield automatically covers the needle when the needle is removed from the skin. Remove the needle from the pen; a second safety shield automatically covers the back end of the needle when removed from the pen. Dispose of the needle in a sharps container.
- Alternatively, patients at home should replace the reserved outer shield on the needle before removing the needle from the pen. Other needle removal devices and procedures exist; patients should follow the instructions provided by their health care provider related to their specific insulin pen.
- Remove gloves and additional PPE, if used.

- Perform hand hygiene.
- Document administration on the eMAR/MAR, including the injection site.

Patient using an insulin pen. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud*.)

FIGURE 30-12. Patient wearing an insulin pump. (Courtesy of Medtronic.)

Technology Alert

Insulin pump therapy can also be integrated with continuous blood glucose monitoring, which allows for responsive insulin administration, downloading of trends and information regarding glucose and insulin needs, and direct transmission of data to health care providers. Many insulin pumps are waterproof and interface with a smartphone.

ADMINISTERING MEDICATIONS INTRAMUSCULARLY

Intramuscular injections deliver medication through the skin and subcutaneous tissues into certain muscles. Muscles have larger and a greater number of blood vessels than subcutaneous tissue, allowing faster onset of action than with

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

subcutaneous injections. Some medications administered intramuscularly are formulated to have a longer duration of effect. The deposit of medication creates a depot at the site of injection, designed to deliver slow, sustained release over hours, days, or weeks. This route is used to administer drugs such as antibiotics, hormones, and vaccines, such as the pneumococcal and hepatitis vaccines. The accompanying box, Through the Eyes of a Student, relates one student's experience administering an intramuscular injection.

Aspiration, or pulling back on the plunger to check if a blood vessel has been entered, is not necessary and has not proved to be a reliable indicator of needle placement. Despite a tradition of aspiration, if correct technique is used and recommended anatomic injection sites are used, the likelihood of injecting into a blood vessel is small and there is no scientific evidence to support aspiration (Centers for Disease Control and Prevention, 2019; Sisson, 2015). The World Health Organization (WHO, 2020) and CDC (2015/2020) do not include aspiration in their steps for intramuscular injection of vaccines. The wide-spread use of auto-disable (AD) syringes encouraged by WHO (2020) further reinforces no aspiration with IM vaccine administration, since most AD syringes are not designed to aspirate (Sepah et al., 2017). In addition, aspiration causes increased pain when performed over the standard 5 to 10 seconds (Sisson, 2015); aspiration, even when performed, is not always performed over the recommended time-frame (Sisson, 2015; Thomas et al., 2016). Some medication manufacturers indicate that aspiration may be recommended when administering certain medications, at certain dosages, at certain rates, but more research needs to be done on this topic in the adult setting (Sepah et al., 2017; Thomas et al., 2016). Consult facility policy and manufacturer recommendations to ensure safe administration.

Through the Eyes of a Student

I entered my patient's room, knowing that she had had surgery less than 12 hours before my arrival, and introduced myself. I asked how she was feeling, to which she immediately responded, "I feel really sick. I think I'm going to throw up. I need something—now!" I told her that I would check the medication orders and be back as soon as possible. I walked quickly to the medication administration record, and there it was glaring at me in black and white on the eMAR: "Prochlorperazine, 10 mg IM q 6 hr PRN nausea or vomiting." My mind raced as I thought, "I have never given an IM injection. There has to be something else prescribed." I knew there wasn't. I found my clinical instructor and announced, "My patient needs an IM injection." Given the anxiety I was feeling, everything went surprisingly well as we prepared the medication. I went over the procedure one last time before entering the patient's room.

We approached the patient just in time for her to look at us in sheer terror and cry, "I hope that shot isn't for me; I hate them," which did nothing for my already shaking hands. I explained that she couldn't take a pill because she could not have anything by mouth because of the nature of her surgery and that this would help. She was agreeable after hearing the rationale. My instructor and I positioned the patient on her side so that I could give her the shot in the (preferred) ventrogluteal area. I marked the landmarks at least half a dozen times, wiped the area with alcohol, and asked her if she was ready for the injection. *Big mistake!* She swiftly replied, "No, but get it over with." I took a minute to reassure her (and silently, me) again.

A little voice in my head repeated the words my *technologies* professor had said a million times, "Darting action is the key to a successful injection." So, I aimed at the bull's-eye that appeared in front of my eyes. My hand, which seemed to be moving in slow motion, propelled downward at a 90-degree angle. Secretly, I prayed that I would not hit my own hand. I looked down and it was a bull's-eye, thank goodness, but the needle had not penetrated the muscle! The patient successfully tensed her muscle tight enough to intercept the needle midflight. At that moment, she relaxed, probably because she thought the worst was over, and I pushed the needle into place. I stabilized the syringe at the end of the barrel, and began injecting the prochlorperazine slowly, watching my hands shake. Then I withdrew the needle, activated the needle safety device, and gently applied pressure over the site. It was over and I wanted to scream, "I did it!" but I kept my composure to feign the experience I lacked. Giving my first IM injection was not as bad as I thought it would be!

—Alison L. Moriarty, Georgetown University, Washington, DC

Intramuscular Injection Sites

Various sites may be used for intramuscular injections. To avoid complications, it is important to be able to identify anatomic landmarks and site boundaries and to use an accurate, careful technique when administering intramuscular injections. If care is not taken, possible complications include abscesses; cellulitis; injury to blood vessels, bones, and nerves; lingering pain; tissue necrosis; and periostitis (inflammation of the membrane covering a bone). Avoid any site that is bruised, tender, hard, swollen, inflamed, or scarred. After using the appropriate landmarks, always palpate the muscle to ensure the location identified is appropriate for each individual patient.

Consider the age of the patient, medication type, and medication volume when selecting a site for intramuscular injection. See Table 30-4 for information related to intramuscular site selection. Rotate the sites used to administer intramuscular medications when therapy requires repeated injections. Whatever pattern of rotating sites is used,

provide a description of it in the patient's plan of nursing care.

The *ventrogluteal site* (see Fig. 30-13A on page 950) involves the gluteus medius and gluteus minimus muscles in the hip area. This site offers a large muscle mass that is relatively free from major nerves and blood vessels, the site is associated with less pain (Şanlialp Zeyrek et al., 2019), the area is clean (fecal contamination is rare at this site), and the patient can be on the back, abdomen, or side for the injection. To relax the gluteal muscle, the patient may flex the knees while lying on the back, point the toes inward while lying in the prone position, and flex the upper leg in front of the lower leg in the side-lying position. Although any of these three positions may be used when injecting into the ventrogluteal site, most nurses prefer the side-lying position.

Table 30-4 Intramuscular Site Selection

CRITERIA	RECOMMENDED SITE
Age of Patient	
Infants and toddlers	Vastus lateralis
Children	Vastus lateralis or deltoid
Adults	Ventrogluteal or deltoid
Medication Type	
Biologicals (infants and toddlers)	Vastus lateralis
Biologicals (children and adults)	Deltoid
Medications that are known to be irritating, viscous, or oily solutions	Ventrogluteal

Source: Adapted from Centers for Disease Control and Prevention (CDC). (2015/2020). Epidemiology and prevention of vaccine-preventable diseases (13th ed.). J. Hamborsky, A. Kroger, & S. Wolfe (Eds.). Public Health Foundation. http://www.cdc.gov/vaccines/pubs/pinkbook/index.html

To locate the ventrogluteal site, place the palm of your hand over the greater trochanter, with your fingers facing the patient's head. The right hand is used for the patient's left hip, or the left hand for the right hip, to identify landmarks. Place the index finger on the anterosuperior iliac spine and extend the middle finger dorsally, palpating the iliac crest. A triangle is formed, and the injection is given in the center of the triangle.

The *vastus lateralis* (see Fig. 30-13B on page 950) involves the quadriceps femoris muscle and is located along the anterolateral aspect of the thigh. There are no large nerves or vessels in its proximity, and it does not cover a joint. To locate the site, divide the thigh into thirds horizontally and vertically and administer the injection in the outer middle third. This space provides a large number of injection sites. The vastus lateralis site is particularly desirable for infants and children, whose gluteal muscles are poorly developed. Caregivers and nurses can use the cuddle position (semi-recumbent on caregiver's lap), the bed position (lying on back), the upright position (lap-sitting), or the straddle position (infant facing the caregiver) to promote access to the preferred site, while keeping the infant still and comforted (WHO, 2020).

The *deltoid muscle* is located in the lateral aspect of the upper arm (see Fig. 30-13C on page 950). It is the recommended site for vaccines for adults and may be used for children between ages 3 and 18 years for vaccine administration (CDC, 2019). The deltoid muscle is not developed enough in infants and toddlers to absorb medication adequately.

Concept Mastery Alert

The deltoid is the recommended site for vaccines for adults. The ventrogluteal site is recommended for general IM injections in adults.

Damage to the radial nerve and artery is a risk with use of the deltoid site. Intramuscular injections into the deltoid muscle should be limited to 1 mL of solution, but up to 2 mL may be administered, depending on the size of the muscle. Locate the deltoid muscle by palpating the lower edge of the acromion process. The deltoid site is typically three finger-breadths below the acromium process. Visualize a triangle formed at the midpoint in line with the axilla on the lateral aspect of the upper arm, with the base of the triangle at the acromion process.

The dorsogluteal site has been previously identified as a possible site to be used for intramuscular medication administration. However, this site has been associated with inadvertent injection into subcutaneous tissue because the area is covered with subcutaneous tissue in many people. Injection into subcutaneous tissue alters drug absorption and can cause tissue irritation, pain, infection, neuropathy, bleeding, abscess formation, or necrosis (Ozen et al., 2019). It is also near the gluteal artery. More importantly, this site has been associated with significant injury, including pain

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and temporary or permanent paralysis, caused by damage to the sciatic nerve and other small nerves (Wu et al., 2020). Therefore, the dorsogluteal site is no longer recommended for use for intramuscular injections (Arslan & Özden, 2018; Frandsen & Pennington, 2021; Sisson, 2015; WHO, 2020). Discontinuing use of this site is linked to the elimination of aspiration during IM injections as routine practice (Sisson, 2015). It should be noted that despite the current recommendations to not use the dorsogluteal site (unless absolutely necessary; CDC, 2019), nurses continue to use this site in practice. Focused education and training on use of the ventrogluteal site increases the knowledge of nurses and may alleviate anxiety and change their opinions of outdated practice traditions (Arslan & Özden, 2018). More research needs to be done to generate definitive empirical evidence and universal, clear guidance on this topic (Brown et al., 2015; CDC, 2015/2020; Mraz et al., 2018). Follow the policies and procedures outlined by your health care facility.

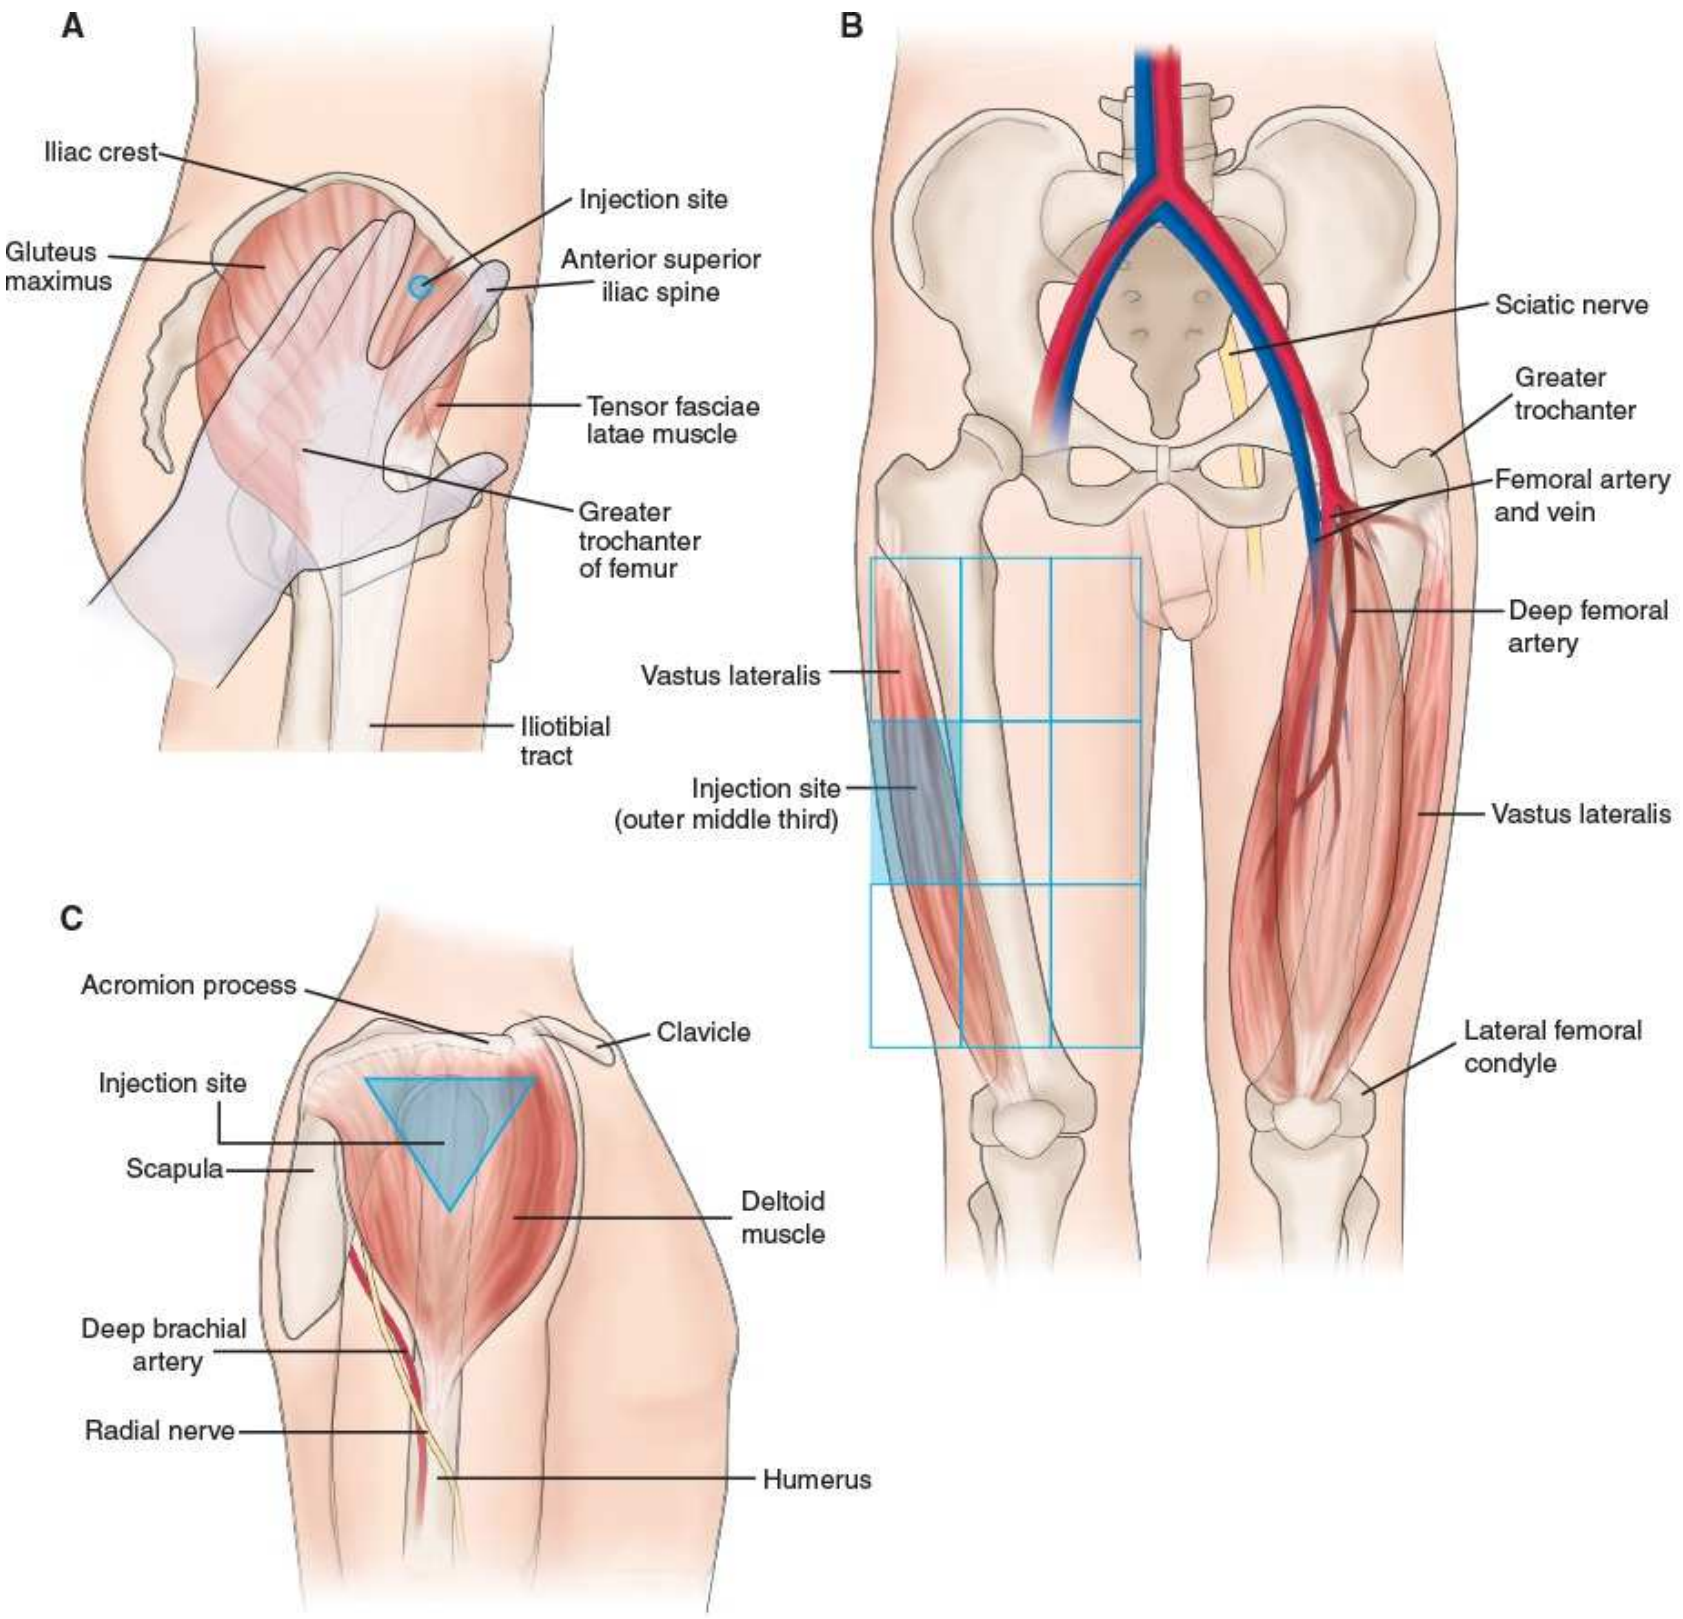

FIGURE 30-13. Sites for intramuscular injections. **A.** The ventrogluteal site is located by placing the palm on the greater trochanter and the index finger toward the anterosuperior iliac spine. **B.** The vastus lateralis site is identified by dividing the thigh into thirds, horizontally and vertically. **C.** The deltoid muscle site is located by palpating the lower edge of the acromion process.

Equipment

It is important to choose the right equipment for a particular intramuscular injection. Needle length should be based on the individual patient (see Table 30-5 for intramuscular needle length recommendations). Patients who are obese may require a longer needle (CDC, 2015/2020) and those who are emaciated may require a shorter needle. Appropriate gauge is determined by the medication being administered. In general, biologic agents and medications in aqueous solutions should be administered with a 20- to 25-gauge needle. Medications in oil-based solutions should be administered with an 18- to 25-gauge needle. Many medications come in prefilled syringe units. If a needle is provided on the prefilled unit, ensure that the needle on the unit is the appropriate length for the patient and situation.

Table 30-5 Intramuscular Injection Needle Length

SITE/AGE[a]	NEEDLE LENGTH
Vastus lateralis	5/8″ to 1″
Deltoid (children)	5/8″ to 1″
Deltoid (adults)	5/8″ to 1½″
Ventrogluteal (adults)	1″ to 1½″

[a]Biologic sex and weight are directly related to needle length choice; the size of the muscle, the adipose tissue thickness at the injection site, the volume of medication to be administered, and the injection technique also need to be considered. (Smart Sense Link: CDC PinkBook: http://www.cdc.gov/vaccines/pubs/pinkbook/vac-admin.html)

Source: Adapted from Centers for Disease Control and Prevention (CDC). (2015/2020). Epidemiology and prevention of vaccine-preventable diseases (13th ed.). J. Hamborsky, A. Kroger, & S. Wolfe (Eds.). Public Health Foundation. http://www.cdc.gov/vaccines/pubs/pinkbook/index.html

Procedure

The volume of medication that can be administered intramuscularly varies based on the intended site. In general, 1 to 5 mL is the accepted volume range. The less-developed muscles of children and older adults limit the intramuscular injection to 1 to 2 mL. Administer the intramuscular injection so that the needle is perpendicular to the patient's body. This should ensure that it is given using a 90-degree angle of injection (CDC, 2019).

Many of the drugs given intramuscularly can cause irritation to subcutaneous tissues when backflow into the tissues occurs along the injection track. Therefore, the **Z-track technique** is recommended for all intramuscular injections (particularly nonvaccine injections) to ensure that medication does not leak back along the needle track and into the subcutaneous tissue (Karch, 2020; Yilmaz et al., 2016). This technique reduces pain and discomfort (Şanlialp Zeyrek et al., 2019), particularly for patients receiving injections over an extended period. The Z-track method is also suggested for older adults who have decreased muscle mass. Some agents, such as iron, are best given via the Z-track method due to the irritation and discoloration associated with this agent (Karch, 2020).

FIGURE 30-14. Spreading the skin taut at ventrogluteal site.

In the Z-track technique, attach a clean needle to the syringe after the syringe is filled with the medication to prevent the injection of any residual medication on the needle into superficial tissues. Pull the skin down or to one side 1 to 2 cm (Yilmaz et al., 2016; Karch, 2020), spread the skin taut at the injection site, and hold in this position with the nondominant hand. Insert the needle and inject the medication slowly. After 10 seconds, withdraw the needle steadily and release the displaced tissue to allow it to return to its normal position. Massage of the site is *not* recommended because it may cause irritation by forcing the medication to leak back into the needle track. However, gentle pressure may be applied with a dry sponge. The procedure for administering an intramuscular injection using the Z-track technique is outlined in Skill 30-7 on pages 996–1002. An alternative method for intramuscular injection is to stretch the skin flat between two fingers and hold it taut for needle insertion. This technique for administering an intramuscular injection is illustrated in Figure 30-14. Figure 30-15 compares the angles for needle insertion for different forms of injections. The decision to simply stretch the skin taut or use the Z-track method is based on the individual patient and clinical judgment. Knowledge of landmarks and risks, along with an assessment of muscle size and consideration of the medication itself, are of paramount importance for the nurse.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

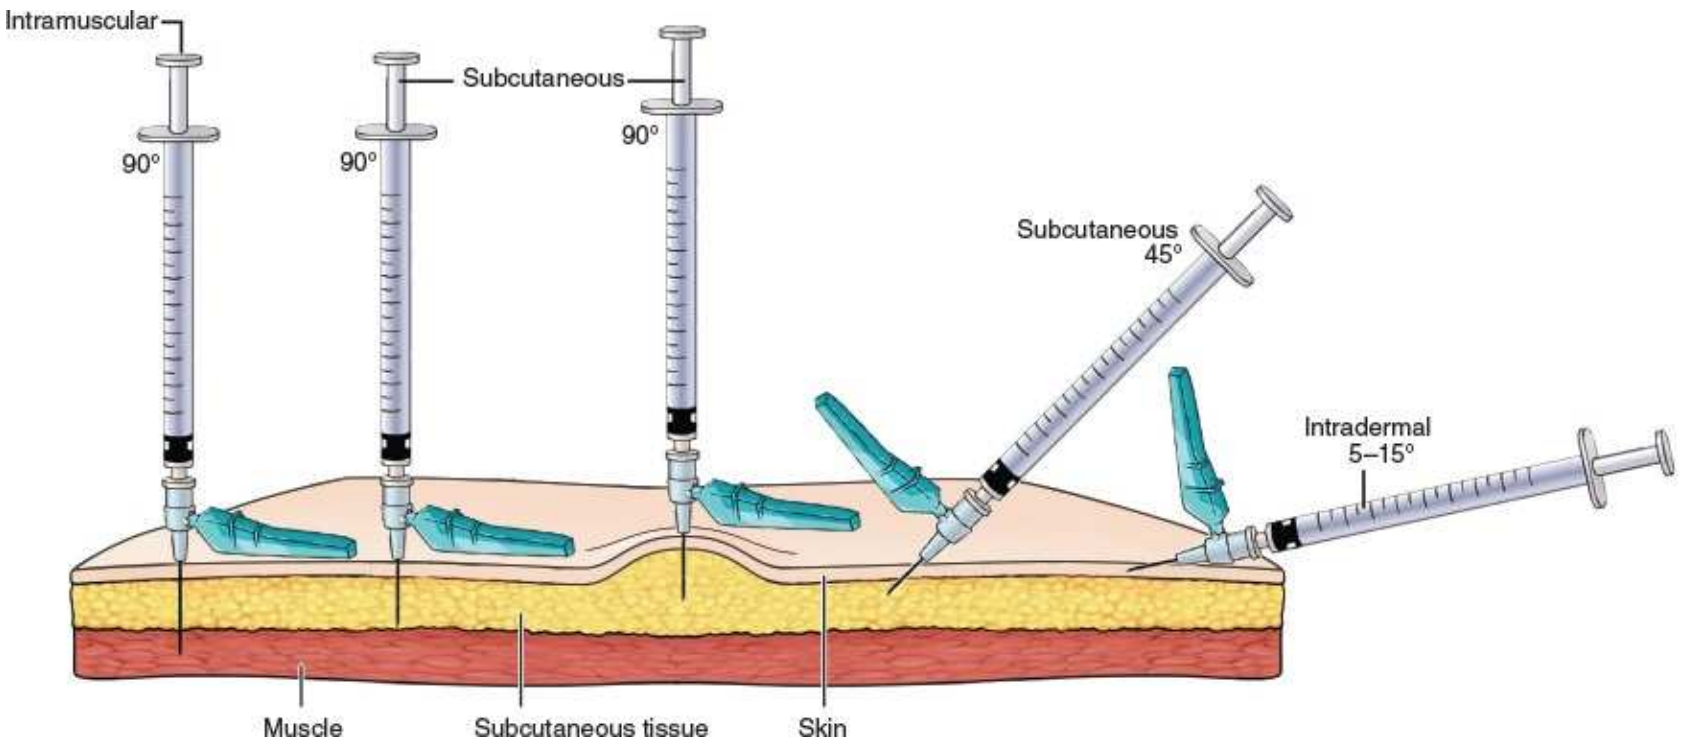

FIGURE 30-15. Comparison of insertion angles for intramuscular, subcutaneous, and intradermal injections.

Several techniques have been suggested as interventions that can be used to reduce discomfort and pain associated with intramuscular injections. The application of manual pressure at the insertion site is one suggestion. Firmly press the insertion site for 10 seconds before needle insertion. This is thought to stimulate the surrounding nerve endings, leading to a reduction in the sensory input from the injection and decreased pain intensity (Şanlialp Zeyrek et al., 2019). Children can be soothed by nonpharmacologic methods such as breastfeeding, the administration of sweet solutions, front-to-front upright holding, rapid injection without aspiration, administration of the most painful vaccine last, tactile stimulation, and distractions (Harrison et al., 2014; Taddio et al., 2010). Box 30-2 on page 946 provides additional techniques for reducing discomfort when injecting medications subcutaneously or intramuscularly.

ADMINISTERING MEDICATIONS INTRAVENOUSLY

Intravenous administration of medications delivers the drug directly into the bloodstream. Medications administered intravenously have an immediate effect. The **intravenous route** is the most dangerous route of administration because the drug is placed directly into the bloodstream, it cannot be recalled, and its actions cannot be slowed. Intravenous administration is the route used in most emergency situations when immediate onset of action is required. There also are many nonemergency clinical situations in which drugs are administered intravenously. Patient-controlled analgesia (PCA) allows the patient to control administration of an intravenous analgesic for pain management (refer to Chapter 35). There are several ways to administer medications intravenously. Observe aseptic technique when administering medications intravenously to prevent introduction of microorganisms.

Medications via Intravenous Solution

Medications may be added to the patient's infusion solution. In most facilities, the pharmacist adds the prescribed drug to a large volume of intravenous solution.

When medication is administered by infusion, the patient receives it at a defined rate (mL/hr) over a defined period of time. IV fluid, such as 0.9% or 0.45% Sodium Chloride, may run continuously at a defined hourly rate. Other medications, such as insulin, vasopressors (increase blood pressure), heparin, or sedatives, are titrated (increased or decreased) depending on specific parameters such as the patient's clinical presentation, blood pressure, or laboratory values. Check the patient receiving medication by a continuous intravenous infusion for possible adverse effects at least every hour or more frequently per unit protocol.

Medications via an Intravenous Bolus or Push

A medication can be administered as an intravenous bolus or push. This involves a single injection of a concentrated solution directly into an intravenous line (Skill 30-8 on pages 1002–1008). Although the administration rate varies, many drugs are administered over a 2-minute time frame. Confirm exact administration times by consulting a pharmacist or drug reference.

Medications via Intermittent Intravenous Infusion

Medications can be administered by intermittent intravenous infusion. The drug is mixed with a small amount of an intravenous solution, such as 50 to 100 mL of saline or dextrose, and administered over a short period at the prescribed interval (e.g., every 4 hours). The administration time is dictated by the dose and classification of the prescribed medication. For example, many antibiotics and electrolytes are administered over 30 to 90 minutes. The administration is most often performed using an intravenous infusion pump, which requires the nurse to program the infusion rate (mL/hr) and prescribed volume into the pump. *Smart (computerized) pumps* are being used by many

facilities for intravenous infusions, including intermittent infusions. Smart pumps also require programming of infusion rates by the nurse, but also are able to identify dosing limits and practice guidelines to aid in safe administration (Institute for Safe Medication Practices, 2020). More information about intravenous infusions and smart pumps is provided in Chapter 41. Administration may be achieved by gravity infusion, which requires the nurse to calculate the infusion rate in drops per minute (gtt/min). The formula for this requires knowledge of the drop factor, which represents the number of drops per mL a specific IV tubing set delivers—this drop factor is determined by the manufacturer and printed on the IV tubing packaging.

$$\frac{\text{Drop Factor (gtt/mL)} \times \text{Volume to be Infused (mL)}}{\text{Time in Minutes (min)}}$$

An easy way to remember this formula is $\frac{D \times V}{M}$ no one relishes going to the DMV, but this acronym is familiar to anyone who has a driver's license in the United States. The calculated flow rate of a medication administered via gravity can be altered when the patient bends the extremity proximal to the intravenous insertion site, lifts the extremity, or has an infiltration at the insertion site. Best practice is to use an intravenous infusion pump whenever possible. Knowing how to calculate drops per minute is invaluable when equipment is scare or in an emergency situation.

As mentioned, the CDC and the Occupational Safety and Health Administration (OSHA) recommend needleless devices. Needleless devices prevent needlesticks and provide access to the primary venous line. Access or connection ports are used to connect intermittent intravenous infusions. A patient with an intravenous line in place can receive the solution containing the medication by way of a piggyback setup, a volume-control administration set (e.g., Pediatrol or Volutrol), or a mini-infusion pump (syringe pump).

Although newer IV pumps allow for more flexibility (including concurrent programming of primary and secondary/piggyback lines), some intravenous **piggyback delivery systems** still require the intermittent or additive solution to be placed higher than the primary solution container. An extension hook provided by the manufacturer provides for easy lowering of the main intravenous container. The port on the primary intravenous line has a back-check valve that automatically stops the flow of the primary solution, allowing the secondary or piggyback solution to flow when connected. Because manufacturers' designs vary, check the directions carefully for the systems used in the facility. Intravenous administration of medications using a gravity-based piggyback setup is explained in Skill 30-9 on pages 1008–1014.

FIGURE 30-16. Volume-control administration set and IV solution for dilution of medication. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

Medications can also be placed in a volume-control administration set for intermittent intravenous infusion. The medication is diluted with a small amount of solution and administered through the patient's intravenous line (Fig. 30-16). This type of equipment may be used for infusing solutions into children, the critically ill, and older adults when the volume of fluid infused is a concern.

The mini-infusion pump (syringe pump) for intermittent infusion is battery operated and allows medication mixed in a syringe to be connected to the primary line (Fig. 30-17). The medication is delivered when the pump applies mechanical pressure to the syringe plunger.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 30-17. Inserting syringe into mini-infusion pump.

A medication or drug infusion lock, also known as an intermittent peripheral venous access device or *saline lock*, is used for patients who require intermittent intravenous medication, but not a continuous intravenous infusion. This device consists of a catheter connected to a short length of extension tubing capped with a sealed injection port. A peripheral venous access device is shown in Skill 30-10 on pages 1015–1020. After the catheter is in place in the patient's vein, anchor the catheter and tubing to the patient's arm so that the catheter remains in place until the patient no longer requires the medication intravenously.

An intermittent peripheral venous access device allows the patient more freedom than a continuous intravenous infusion. The patient is connected to the intravenous line when it is time to receive the medication and disconnected when the medication is completed. It is important to keep the device patent (working) by flushing with small amounts of saline pushed through the device on a routine basis. Do not start an intermittent infusion until intravenous placement is confirmed. Flush the peripheral venous access device before the infusion is begun and after the infusion is completed to clear the vein of any medication and to prevent clot formation in the catheter. The procedure for flushing this device with saline is discussed in Skill 30-10 on pages 1015–1020. A medication prescribed as an intravenous bolus or push (discussed on page 1012) may also be administered via a medication lock (refer to Skill 30-10). Assess the intravenous site for complications (see Chapter 41). If infiltration or phlebitis occurs, remove the device and insert a new catheter in a new site.

In addition to a peripheral intravenous line, intermittent intravenous medication may be administered through a central venous access device (CVAD). Many of these devices have particular specifications to be followed when using for administration of fluids or medication. It is important to be aware of the specifics for the device being used. Facilities have specific policies in place for reference. CVADs are discussed in more detail in Chapter 41.

Administering Topical Medications

Medications delivered via the topical route are applied to the skin or mucous membranes, including the eyes, ears, nose, rectum, vagina, and lungs. **Topical applications** are usually intended for direct action at a particular site, although some can have systemic effects and may be prescribed for that systemic effect. The action depends on the type of tissue and the nature of the agent.

If the site of application is readily accessible, such as the skin, an agent can easily be placed onto it. If it is a cavity, such as the nose, or is enclosed, such as the eye, a mechanical applicator may be needed to introduce the drug. Topical medications should not be shared. For medications administered routinely, patients in the hospital will have their own medications labeled with their names for individual use.

SKIN APPLICATIONS

The skin is a mechanical and chemical barrier that protects the underlying tissues. It is a sense organ, with receptors that respond to touch, pain, pressure, and temperature. The skin helps in excretion, in regulating body temperature, and in storing essentials to the body such as water, salts, and glucose.

Box 30-3 Typical Preparations Applied to the Skin

Preparation	Use	Nursing Considerations
Powder	Promote drying of the skin. Prevent friction on the skin.	Use caution when applying to prevent inhalation of the powder. Apply powder to the gauze square, then apply to the desired site to minimize inhalation of the airborne particles.
Ointment	Provide prolonged contact of a medication with the skin. Soften the skin.	Massage thoroughly into intact skin.
Creams and oils	Lubricate and soften skin. Prevent drying of skin.	When applying to large parts of the body, warm preparation in the hand or fingers to prevent the patient from experiencing chilling.
Lotions	Protect and soothe the skin.	Shake thoroughly before using. Apply with cotton balls or gauze.
Transdermal: reservoirs, microreservoirs, adhesives, matrices	These systems contain multiple layers, each with a specific job. An impermeable backing prevents drug diffusion from the exposed portion. The drug layer of the system contains drug, with a rate-controlling layer (or microneedles) to slow the release of the drug over time, ending with an adhesive layer to enhance the attachment of the system to the patient's skin (Rabiei et al., 2020).	Wear gloves. Handle by edges to avoid touching drug when handling system. Rotate application sites to avoid skin irritation.

When a drug is incorporated in an agent such as an ointment and rubbed into the skin for absorption, the procedure is referred to as an inunction. On intact skin, drugs are absorbed into the lining of the sebaceous glands. Absorption is hindered because of the protective outer layer of the skin, which makes penetration difficult, and because of the fatty substances that protect the lining of the glands. Cleaning the skin thoroughly with soap or detergent and water before administration and then rubbing the medicated preparation into the skin can enhance absorption. Absorption can also be improved by using a drug mixed in an ointment or added to a liniment that will mix with the fat in the gland lining. When indicated, local heat applied to the application area can improve blood circulation and promote absorption. To prevent any absorption by the nurse's skin, wear gloves during the application of topical medications. Refer to Box 30-3 for information related to typical preparations applied to the skin.

The transdermal route is being used more frequently to deliver medication. This involves applying to the skin a

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

disk or patch that contains medication intended for daily use or for longer intervals. Transdermal patches are commonly used to deliver hormones, narcotic analgesics, cardiac medications, and nicotine. These devices should not be massaged or moistened, have heat or cold applied, or be kept on during procedures such as an MRI or defibrillation. Transdermal patches that contain estrogen should not be applied to breast tissue due to the associated risks of breast cancer. Medication errors have occurred when patients applied multiple patches at once or failed to remove the overlay on the patch that exposes the skin to the medication. Opioid analgesic patches are associated with the most adverse drug effects and require careful monitoring for advancing sedation and respiratory depression (Jungquist et al., 2020; see Chapter 36 for more information on opioids). Clear patches have a cosmetic advantage but can be difficult to find on the patient's skin when they need to be removed or replaced. Despite a slow onset of action, transdermal drug patches maintain consistent serum drug levels. See Guidelines for Nursing Care 30-2: Applying Transdermal Patches.

EYE INSTILLATIONS AND IRRIGATIONS

The receptors for the sense of sight are located in the eye. The outer layer of the eyeball is called the sclera (the white of the eye). The cornea is the transparent part of the sclera in front of the eyeball. The sclera is fibrous and tough, but the cornea is injured easily by trauma. For this reason, applications to the eye seldom are placed directly onto the eyeball. Because direct application cannot be made onto the sensitive cornea, applications intended to act on the eye or the lids are placed onto, or instilled or irrigated into, the lower conjunctival sac.

The eye is a delicate organ, highly susceptible to infection and injury. Although the eye is never free of microorganisms, the secretions of the conjunctiva have a protective action against many pathogens. For maximum safety for the patient, the equipment, solutions, and ointments introduced into the conjunctival sac should be sterile. If this is not possible, follow the most careful guidelines for medical asepsis.

Eye Drops

Eye drops are instilled for their local effects, such as for pupil dilation or constriction when examining the eye, for treating an infection, or for controlling intraocular pressure in patients with glaucoma. The type and amount of solution depend on the purpose of the instillation. See Guidelines for Nursing Care 30-3: Instilling Eye Drops on page 956.

Guidelines for Nursing Care 30-2

Applying Transdermal Patches

- Perform hand hygiene and put on PPE, as indicated.

- **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two methods** (The Joint Commission, 2020a).
- **Complete necessary assessments before administering medications. Check the patient's allergy bracelet or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**
- Scan the patient's bar code on the identification band, if required.
- **Based on facility policy, the third check of the label may occur at this point. If so, recheck the labels with the eMAR/MAR before administering the medications to the patient.**
- Put on gloves.
- Assess patient's skin where patch is to be placed, looking for any signs of irritation or breakdown. Site should be clean, dry, and free of hair. Rotate application sites.
- **Remove any old transdermal patches of the same medication from the patient's skin.** Fold patch in half with adhesive sides sticking together and discard according to facility policy.
- Gently wash the area where the old patch was.
- Remove the patch from its protective covering.
- Remove the covering on the patch without touching the medication surface. Apply the patch to the patient's skin. Smooth the edges down, and use the palm of your hand to press firmly for 30 seconds. Do not massage.
- Depending on facility policy, initial and write the date and time of administration on a piece of medical tape. Apply the tape to the patient's skin in close proximity to the patch. **Do not write directly on the medication patch.**

- Remove gloves and additional PPE, if used. Perform hand hygiene.
- Document the administration of medication immediately after administration including date, time, dose, route of administration, and site of administration on eMAR/MAR or record.
- Evaluate patient's response to medication within appropriate time frame for early detection of adverse effects.
- Check for dislodgement of the patch if the patient is active. Read information about the patch or consult with the prescriber or pharmacist to determine reapplication schedule and procedure.
- Assess for any skin irritation at application site. If necessary, remove the patch, wash the area carefully, and allow skin to air dry. Apply a new patch at a different site. Assess the potential for adverse reaction.
- Aluminum backing on a patch necessitates precautions if defibrillation is required. Burns and smoke may result. These patches should be removed before an MRI is performed to avoid burning of the skin.

Ointments

Various types of medication in ointment form may be prescribed for the eye. These ointments are usually used for a local infection or irritation. Eye ointments are dispensed in a tube. A small amount of ointment is distributed along the exposed lower conjunctival sac after the eyelids and eyelashes have been cleansed. About ½ inch of ointment is squeezed from the tube along the exposed sac moving from the inner canthus to the outer canthus of the eye. After the application, the eyes should be closed. The warmth helps to liquefy the ointment. Instruct the patient to move the eye because this helps to spread the ointment under the lids and over the surface of the eyeball. Explain that the ointment may temporarily blur vision; encourage the patient not to rub the eye.

Eye Irrigation

Eye irrigation is performed to remove secretions or foreign bodies or to cleanse and soothe the eye. In an emergency, eye irrigation can be used to remove chemicals that may burn the eye. Copious amounts of tap water should be used to remove chemicals such as acid. The irrigation should continue for at least 15 minutes, and then professional help should be sought. Many emergency departments have eye flush stations to help with eye irrigations. Care should be taken so that the overflowing irrigation fluid does not contaminate the other eye.

Eye Medication Disks

An eye medication disk is flexible and resembles a small contact lens. These disks contain medication that is released gradually into the conjunctival sac. Once applied, the disk remains in place for as long as a week before being removed and discarded. When properly placed, the disk is completely covered by the lower eyelid, allowing the patient to wear contact lenses, swim, and sleep with the disk in place. Eye medication disks are usually applied at bedtime because they initially cause blurring of vision.

EAR INSTILLATIONS AND IRRIGATIONS

The ear contains the receptors for hearing and equilibrium. It consists of the external ear, the middle ear, and the inner ear. The external ear consists of the auricle or pinna and the exterior auditory canal. The auditory canal serves as a passageway for sound waves. Drugs or irrigations are instilled into the auditory canal for their local effect. They are used to soften wax, relieve pain, apply local anesthesia, destroy organisms, or destroy an insect lodged in the canal, which can cause almost intolerable discomfort. If the ear canal has swollen to the point that medication cannot pass, a long piece of cotton material called a wick is inserted so that one end is near the middle ear and the other end is external to the ear. This cotton then acts as a wick to help medication get into the canal.

Guidelines for Nursing Care 30-3

Instilling Eye Drops

- Perform hand hygiene.

- **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two methods** (The Joint Commission, 2020a).
- **Complete necessary assessments before administering medications. Check the patient's allergy bracelet or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**
- Scan the patient's bar code on the identification band, if required.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- **Based on facility policy, the third check of the label may occur at this point. If so, recheck the labels with the eMAR/MAR before administering the medications to the patient.**
- Put on gloves.
- Offer the patient paper tissues to remove solution and tears that may spill from the eye during the procedure.
- Clean the eyelids and eyelashes of any drainage with cotton balls or gauze squares moistened with water or normal saline solution, as needed. Debris can be carried into the eye when the conjunctival sac is exposed. Use each area of the cleaning surface once, moving from the inner toward the outer canthus to prevent carrying debris to the lacrimal ducts.
- Tilt the patient's head back slightly if sitting, or place the patient's head over a pillow if lying down. **Tilting the patient's head should be avoided if the patient has a condition that limits range of motion.** The head may be turned slightly to the affected side to prevent solution or tears from flowing toward the opposite eye.
- Remove the cap from the medication bottle, being careful not to touch the inner aspect of the cap or the tip of the bottle.
- Invert the monodrip plastic container that is commonly used to instill eye drops.
- Have the patient look up while focusing on something on the ceiling.
- Place the thumb or two fingers near the margin of the lower eyelid immediately below the eyelashes, and apply pressure downward over the bony prominence of the cheek. The lower conjunctival sac is exposed as the lower lid is pulled down.
- **Hold the dropper close to the eye but avoid touching the eyelids or lashes.** Rest the lateral side of your hand on the patient's forehead, just above the eyebrow, as needed for stability. Touching the eye, eyelids, or lashes can contaminate the medication in the bottle, startle the patient, causing blinking, or injure the eye.
- Squeeze the container and allow the prescribed number of drops to fall in the lower conjunctival sac. Do not allow medication to fall onto the cornea. This may injure the cornea or cause the patient to have an unpleasant sensation.
- Release the lower lid after the eye drops are instilled. Ask the patient to close the eyes gently.
- Apply gentle pressure with your gloved finger over the inner canthus to prevent the eye drops from flowing into the tear duct. This minimizes the risk of systemic effects from the medication.
- Replace the cover on the medication bottle.
- Instruct the patient not to rub the affected eye.
- Remove gloves and additional PPE, if used. Perform hand hygiene and assist the patient to a comfortable position.
- Document the administration of medication immediately after administration including date, time, dose, route of administration, and site of administration on the eMAR/MAR or record.
- Evaluate the patient's response to the medication within the appropriate time frame.

With the lower lid pulled down, the nurse prepares to administer the eye drops on the lower conjunctival sac.

The tympanic membrane separates the external ear from the middle ear. Normally, it is intact and closes the entrance to the middle ear completely. If it is ruptured or has been opened by surgical intervention, the middle ear and the inner ear have a direct passage to the external ear. When this occurs, instillations and irrigations should be performed with the greatest of care to prevent forcing materials from the outer ear into the middle ear and the inner ear. Sterile technique is used to prevent infection.

Ear Drops

Follow the techniques listed in Guidelines for Nursing Care 30-4: Instilling Ear Drops when placing drops in the external auditory canal.

Guidelines for Nursing Care 30-4

Instilling Ear Drops

- Perform hand hygiene and put on PPE, as indicated.

- **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two methods** (The Joint Commission, 2020a).
- **Complete necessary assessments before administering medications. Check the patient's allergy bracelet or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**
- Scan the patient's bar code on the identification band, if required.
- **Based on facility policy, the third check of the label may occur at this point. If so, recheck the labels with the eMAR/MAR before administering the medications to the patient.**
- Put on gloves.
- Clean the external ear of drainage with cotton balls moistened with water or normal saline solution, as needed.
- Place the patient on the unaffected side in bed, or if ambulatory, have the patient sit with the head well tilted to the side so that the affected ear is pointed upward. This positioning prevents the drops from escaping from the ear.
- Remove the cap from the medication bottle, being careful not to touch the inner aspect of the cap or the tip of the container.
- Straighten the auditory canal by pulling the cartilaginous portion of the pinna up and back in an adult (Fig. A), straight back for a child older than 3 (Fig. B), and down and back in an infant or a child under age 3 years (Fig. C). Pulling on the pinna as described helps to straighten the canal properly for ear instillation.
- Invert and hold the dropper in the ear with its tip above the auditory canal.
- **Squeeze the bottle and allow drops to fall on the side of the canal. Avoid instilling in the middle of the canal, to avoid instilling directly onto the tympanic membrane.**
- Release the pinna after instilling the drops, and have the patient maintain the position to prevent the medication from escaping.
- Gently press on the tragus a few times to help move the medication from the canal toward the tympanic membrane.
- If ordered, loosely insert a cotton ball to prevent medication from leaking out.
- Replace the cap on the medication bottle.
- Instruct patient to remain lying down with the affected ear upward for 5 minutes. Wait 5 minutes before instilling drops in the second ear, if prescribed.
- Remove gloves and additional PPE, if used. Perform hand hygiene and assist the patient to a comfortable position.
- Document the administration of medication immediately after administration including date, time, dose, route of administration, and site of administration on the eMAR/MAR or record.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

A. Adult patient positioned for ear drop instillation; nurse straightens the auditory canal by pulling the cartilaginous portion of the pinna up and back. **B**. School-aged child positioned for ear drop instillation; nurse straightens the auditory canal by pulling the cartilaginous portion of the pinna straight back. **C**. Child younger than age 3 years ready for ear drop instillation; the nurse straightens the auditory canal by pulling the cartilaginous portion of the pinna down and back. Child can be held by parent.

EAR IRRIGATIONS

Irrigations of the external auditory canal are ordinarily done for cleaning purposes or for applying heat to the area. Typically, normal saline solution is used, although an antiseptic solution may be indicated for local action. To prevent pain, the irrigation solution should be at least at room temperature. An irrigation syringe is used in most instances. An irrigating container with tubing and an ear tip may also be used, especially if the purpose of the irrigation is to apply heat to the area.

NASAL INSTILLATIONS

Besides serving as the olfactory organ, the nose functions as an airway to the lower respiratory tract and protects the tract by cleaning and warming the air taken in by inspiration. Cilia project on most of the surfaces of the nasal mucous membrane, which help remove particles of dirt and dust from the inspired air. The nose also serves as a resonator when speaking and singing.

Nasal instillations are used to treat allergies, sinus infections, and nasal congestion. Medications with a systemic effect, such as vasopressin or naloxone, may also be prepared as a nasal instillation. The nose is normally not a sterile cavity, but, because of its connection with the sinuses, it is important to observe medical asepsis carefully when using nasal instillations. See Guidelines for Nursing Care 30-5: Instilling Nose Spray.

Medications may also be applied to the nasal mucous membrane via nasal drops. The patient should blow the nose before instilling the drops. Have the patient sit up with head tilted well back and maintain this position for a few minutes after instillation. This position allows the solution to flow well back into the nares. Hold up the tip of the nose and place the dropper just inside the naris, about one third of an inch, without touching the naris. Instill the prescribed number of drops in one naris and then into the other. Avoid touching the nares with the dropper; inadvertent contact may cause the patient to sneeze and contaminate the dropper.

▶ Guidelines for Nursing Care 30-5

Instilling Nose Spray

- Perform hand hygiene and put on PPE, as indicated.

- **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two methods** (The Joint Commission, 2020a).
- **Complete necessary assessments before administering medications. Check the patient's allergy bracelet or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**
- Scan the patient's bar code on the identification band, if required.
- **Based on facility policy, the third check of the label may occur at this point. If so, recheck the labels with the eMAR/ MAR before administering the medications to the patient.**
- Put on gloves.
- Provide the patient with paper tissues and ask that the patient blow the nose before instilling the nose drops.
- Have the patient sit up with head tilted back. **Tilting the patient's head should be avoided if the patient has a condition that limits range of motion.**
- Instruct the patient that, depending on the medication, it may be necessary to inhale gently through the nose as the spray is being administered.
- Agitate the bottle gently, if required for specific medication. Insert the tip of the nose piece of the bottle into one nostril.
- Close the opposite nostril with a finger. Instruct the patient to breathe in gently through the nostril, if required. Compress or activate the bottle to release one spray at the same time the patient breathes in.
- Keep the medication container compressed and remove from the nostril. Release the container from the compressed state. Do not allow the container to return to its original position until it is removed from the patient's nose.
- Instruct the patient to hold their breath for a few seconds, and then breathe out slowly through the mouth. Repeat in the other nostril, as prescribed or indicated.
- Wipe the outside of the bottle nose piece with a clean, dry tissue or cloth and replace the cap. Instruct the patient to avoid blowing the nose for 5 to 10 minutes, depending on the medication.
- Remove gloves and additional PPE, if used. Perform hand hygiene and assist the patient to a comfortable position.
- Document the administration of medication immediately after administration including date, time, dose, route of administration, and site of administration on the eMAR/MAR or record.

Inserting tip of bottle into nostril. (*Source:* Craven, R. F., Himle, C. J., & Henshaw, C. M. [2017]. Fundamentals of Nursing: Human Health and Function [8th ed]. Wolters Kluwer.)

Guidelines for Nursing Care 30-6

Inserting Vaginal Cream or Suppository

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

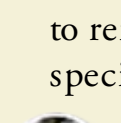
- Perform hand hygiene and put on PPE, if indicated.

- **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two methods** (The Joint Commission, 2020a).
- **Complete necessary assessments before administering medications. Check the patient's allergy bracelet or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**
- Scan the patient's bar code on the identification band, if required.
- **Based on facility policy, the third check of the label may occur at this point. If so, recheck the labels with the eMAR/ MAR before administering the medications to the patient.**
- Ask the patient to void before inserting medication.
- Put on gloves.
- Position the patient so that they are lying on their back with knees flexed. Maintain privacy with draping. Provide adequate light to visualize vaginal opening.
- Perform perineal care. Spread labia with fingers and clean area at vaginal orifice. Wipe from front to back, using a different portion of the disposable cloth/washcloth with each stroke.
- Remove gloves and put on new gloves.
- Fill a vaginal applicator with the prescribed amount of cream, or have a suppository ready (Fig. A).
- Lubricate the applicator with lubricant, as necessary. The rounded end of a suppository may be lubricated with a water-soluble lubricant (Fig. B).
- For a vaginal cream, spread the labia and introduce the applicator gently in a rolling manner while directing it downward and backward to follow the normal contour of the vagina for its full length. Push the plunger to its full length, then gently remove the applicator with the plunger depressed. For a vaginal suppository, lubricate your gloved index finger on your dominant hand. Spread the labia and insert the rounded end of the suppository along the posterior wall of the canal to the length of your finger.
- **Ask the patient to remain in the supine position for a minimum of 5 to 10 minutes after insertion.**
- Offer the patient a perineal pad to collect drainage.
- Remove gloves and additional PPE, if used. Perform hand hygiene and assist the patient to a comfortable position.
- Document the administration of medication immediately after administration including date, time, dose, route of administration, and site of administration on the eMAR/MAR or record.

A. Filling vaginal applicator with cream. **B.** Lubricating vaginal suppository.

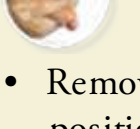
VAGINAL APPLICATIONS

A healthy vagina contains few pathogens, but many nonpathogenic organisms. The nonpathogens are important because they protect the vagina from the invasion of pathogens. The normal secretions in the vagina are acidic and further serve to protect the vagina from microbial invasion. Therefore, the normal mucous membrane is its own best protection.



Creams, foams, and tablets can be applied intravaginally using a narrow, tubular applicator with an attached plunger. Suppositories that melt when exposed to body heat are also administered by vaginal insertion. Refrigerate suppositories for storage. Evidence shows that perineal talc use and the instillation of non-prescription douches—

incorrectly presumed to clean the vagina after menstruation, minimize the contraction of sexually transmitted infections (STIs), or prevent pregnancy—are contraindicated and may lead to vaginal and endometrial infections; pelvic inflammatory disease; pregnancy complications; and cervical, uterine, and endometrial cancers (Gondwe et al., 2020; Hamoonga et al., 2019; O'Brien et al., 2019).



Ask the patient to void before inserting the medication. Position the patient so that they are lying on their back with knees flexed. Maintain privacy with draping. Provide adequate light to visualize the vaginal opening. See Guidelines for Nursing Care 30-6: Inserting Vaginal Cream or Suppository.

Guidelines for Nursing Care 30-7

Inserting A Rectal Suppository

- Perform hand hygiene and put on PPE, if indicated.

- **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two methods** (The Joint Commission, 2020a).
- **Complete necessary assessments before administering medications. Check the patient's allergy bracelet or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**
- Scan the patient's bar code on the identification band, if required.
- **Based on facility policy, the third check of the label may occur at this point. If so, recheck the labels with the eMAR/MAR before administering the medications to the patient.**
- Put on gloves.
- Assist the patient to their left side in a Sims position. Drape accordingly to expose only the buttocks.
- Remove the suppository from its wrapper. Apply lubricant to the rounded end. Lubricate the index finger of your dominant hand.
- Separate the buttocks with your nondominant hand and instruct the patient to breathe slowly and deeply through the mouth while the suppository is being inserted.
- Using your index finger, insert the suppository, round end first, along the rectal wall. Insert about 3 to 4 inches.
- Use toilet tissue to clean any stool or lubricant from around the anus. Release the buttocks. Encourage the patient to remain on their side for at least 5 minutes and retain the suppository for the appropriate amount of time for the specific medication.

- Remove gloves and additional PPE, if used. Perform hand hygiene and assist the patient to a comfortable position.
- Document the administration of medication immediately after administration including date, time, dose, route of administration, and site of administration on the eMAR/MAR or record.

RECTAL INSTILLATIONS

Rectal suppositories and enemas are used primarily for their local action, such as laxatives and fecal softeners. Systemic effects are also achieved with rectal suppositories. Acetaminophen suppositories are used for an antipyretic effect, and many antiemetics are available in suppository form to relieve nausea and vomiting. Do not administer suppositories to patients who have had recent rectal or prostate surgery. Assess recent laboratory values, particularly the patient's white blood cell and platelet counts. Patients who have thrombocytopenia or are neutropenic should not receive rectal suppositories. Do not administer rectal suppositories to patients at risk for cardiac arrhythmias due to the risk of a vasovagal response. Rectal douching, like vaginal douching, is not recommended, but additional research is needed to better understand the risks, associations with STIs and HIV transmission, social and cultural practices, and sexual contexts of rectal douching, which is practiced by men who have sex with men (MSM) and transwomen (Dangerfield II et al., 2020; Reeders et al., 2020).

Use clean disposable gloves to prevent contamination with feces and microorganisms. Refer to Guidelines for Nursing Care 30-7: Inserting a Rectal Suppository. After the suppository is inserted, the patient should remain in that position for 5 minutes. If the suppository is for laxative purposes, it must remain in position for 35 to 45 minutes, or until the patient feels the urge to defecate.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Administering Medications by Inhalation

Drugs for **inhalation** are aerosolized, delivered in small particles, and breathed in by the patient. The lungs are supplied richly with blood and have a large surface area. These characteristics allow drugs to be absorbed easily from the lower respiratory tract. Inhalation may be used to administer several different classes of drugs with varying properties and indications. The smaller the particles of inhaled medication, the lower in the respiratory tract the medication tends to travel. A disadvantage of using this route is that the drug dosage is difficult to establish.

Drugs classified as bronchodilators are an example of a medication administered by inhalation. Bronchodilators act to decrease resistance to airflow by enlarging air passageways. Bronchodilators promote relaxation of musculature in the tracheobronchial tree. The relaxed passages produce less resistance to airflow and provide an opened respiratory passageway. Bronchodilators are further discussed in Chapter 40.

Drugs for inhalation may be administered at home, in the hospital, or in another facility by a nebulizer. Nebulizers facilitate administration of the medication by dispersing the liquid medication in compressed air (*medical air*) or high-flow oxygen. This method is valuable for patients who require inhalation of a drug several times a day when the hand atomizer is fatiguing. Infants and toddlers can also benefit from nebulized medications. With the use of an oxygen mask, children can receive medications with minimal interruption of their activities. Oxygen masks for the pediatric population come in a variety of sizes and also have cute animals on them to make the mask less intimidating for the child. The oxygen stream is also useful in the production of vapors when high humidity is needed continuously for long periods. Refer to the Guidelines for Nursing Care 30-8.

Guidelines for Nursing Care 30-8

Using an Inhaled Medication Device

- Assess the patient's ability to manage a metered-dose inhaler, dry powder inhaler, or small-volume nebulizer.
- Explain, demonstrate, and encourage the patient to manipulate the inhaler or nebulizer apparatus.
- Encourage the patient to wash hands thoroughly before using device.

- Perform hand hygiene.

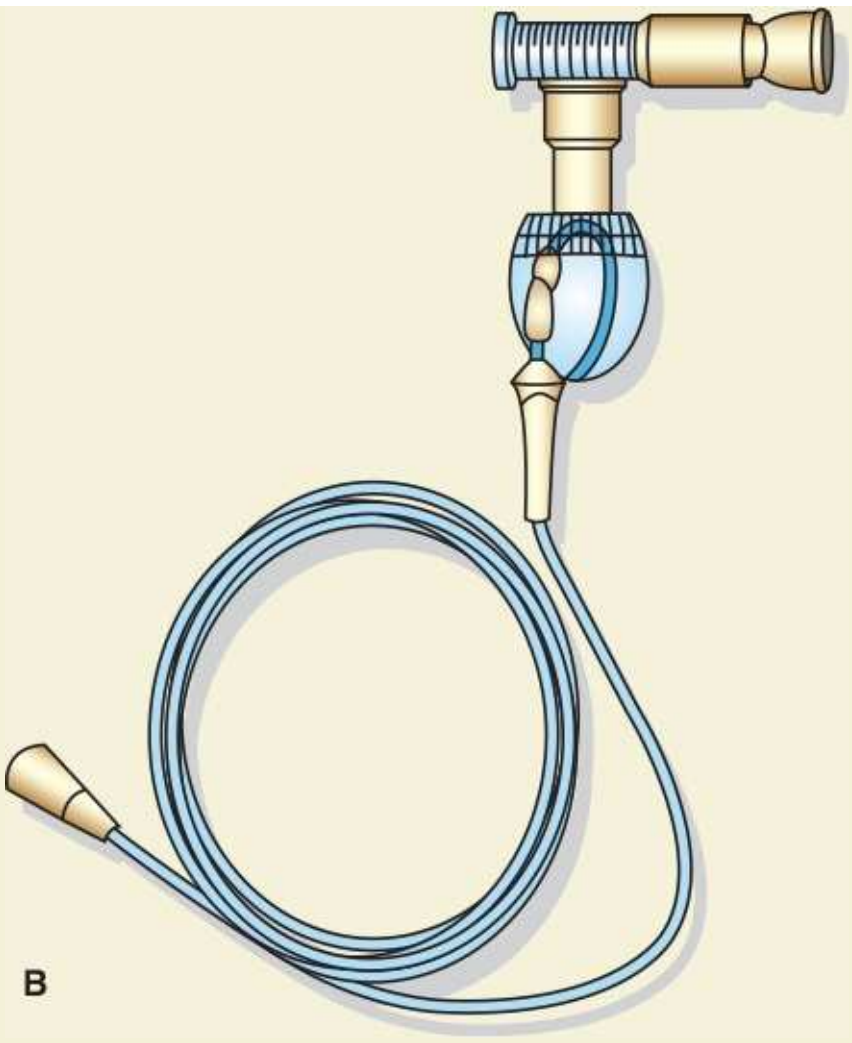
- **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two methods** (The Joint Commission, 2020a).
- **Complete necessary assessments before administering medications. Check the patient's allergy bracelet or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**
- Scan the patient's bar code on the identification band, if required.
- **Based on facility policy, the third check of the label may occur at this point. If so, recheck the labels with the eMAR/MAR before administering the medications to the patient.**

Metered-Dose Inhaler (MDI)

- Shake the inhaler well.
- Remove the mouthpiece covers from the MDI and the spacer. Attach the MDI to the spacer by inserting it in the open end of the spacer, opposite the mouthpiece.
- Have the patient place the spacer's mouthpiece into their mouth, grasping securely with the teeth and sealing the lips tightly around the mouthpiece lips. Have the patient breathe normally through the spacer.
- If no spacer is used, patient takes a deep breath, exhales, holds the inhaler between the lips or 1 to 2 inches away from the mouth (based on guidance from the provider and manufacturer), inhales slowly and deeply while depressing the medication canister and continues to inhale for a full breath.
- Have the patient breathe normally through the spacer.

A. Patient using a metered-dose inhaler with a spacer.

- Instruct the patient to exhale completely, then depress the canister once, releasing one puff into the spacer, and inhale slowly and deeply through the mouth. **Instruct the patient to hold their breath for 5 to 10 seconds, or as long as possible, then to exhale slowly through pursed lips.**
- **Wait 1 to 5 minutes, as indicated by the medication, before administering the next puff, as prescribed.**
- After the prescribed number of puffs has been administered, have the patient remove the MDI from the spacer and replace the caps on both the MDI and spacer.
- Have the patient gargle and rinse with tap water after using an MDI, as indicated. Clean the MDI according to the manufacturer's directions.



Dry Powder Inhaler (DPI)

- Review the specific instructions the specific DPI to be administered.
- Remove the mouthpiece cover (if present) and load a dose if necessary. Alternatively, activate the inhaler, if necessary, according to the manufacturer's directions.
- Have the patient breathe out slowly and completely, without breathing into the DPI. **The patient should place teeth over, and seal lips around, the mouthpiece. It is important to not block the opening with the tongue or teeth.**
- **Have the patient breathe in strong, steady, and deeply through the mouth, for longer than 2 to 3 seconds.**
- Remove the inhaler from the mouth. Instruct the patient to hold their breath for 5 to 10 seconds, or as long as possible, and then to exhale slowly through pursed lips.
- Wait 1 to 5 minutes, as indicated by the medication, before administering the next puff. After the prescribed amount of puffs has been administered, have the patient replace the cap or storage container.
- Have the patient gargle and rinse with tap water after using a DPI, as indicated. Clean the DPI according to the manufacturer's directions.

Small-Volume Nebulizer

- Remove the nebulizer cup from the device and open it.
- Place premeasured unit dose medication in the bottom section of the cup or use a dropper to place concentrated dose of medication in the cup and add prescribed fluid to dilute if required.
- Screw the top portion of the nebulizer cup back in place and attach the cup to the nebulizer.
- Attach one end of tubing to the stem on the bottom of the nebulizer cuff and the other end to the air compressor or oxygen source.
- Turn on the air compressor or oxygen.
- Check that a fine medication mist is produced by opening the valve.
- Have the patient place the mouthpiece into mouth and grasp securely with teeth and lips.
- **Instruct the patient to inhale slowly and deeply through the mouth and hold each breath for a slight pause before exhaling. (A nose clip may be necessary if the patient is also breathing through the nose.)**

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

B. Small-volume nebulizer.

- Have patient continue this inhalation technique until all medication in the nebulizer cup has been aerosolized (usually about 15 minutes). When the medication in the nebulizer cup has been completely aerosolized, the cup will be empty.
- Have the patient remove the nebulizer from the mouth, and gargle and rinse with tap water, as indicated. Clean and store the nebulizer according to the manufacturer's directions and facility policies.

Home Considerations

- Patients should know how to tell when medication levels are getting low. The most reliable method is to look on the canister and see how many puffs the canister contains. Divide this number by the number of puffs used daily to ascertain how many days the MDI will last. For instance, if the MDI contains 200 puffs and the patient takes 6 puffs per day, the MDI should last for 33 days. Keep a diary or record of inhaler use and discard the inhaler on reaching the labeled number of doses. This method may be cumbersome and impractical for some patients, but it is a reliable way to determine how much medication remains in an MDI. Another accurate way to know when the canister is depleted is to use a dose counter, which counts down each time the canister is activated (Cleveland Clinic, 2020). **Floating the canister in water is not reliable and is contraindicated. Immersion in water can cause valve obstruction and threatens product integrity** (MedlinePlus, 2020).
- The plastic holder provided with the inhaler should be cleaned at least weekly. Remove the medication canister and clean with warm running water. Shake the holder and allow to air dry. Some medication canisters cannot be removed from the plastic holder. Wipe the mouthpiece with a cloth or dry cotton swab and/or refer to the manufacturer's directions for cleaning (Cleveland Clinic, 2020). Clean the spacer once a week by soaking in warm water with a mild detergent. Rinse well and shake off excess water. Allow to air dry (Cleveland Clinic, 2020). Do not store spacer in a plastic bag to prevent moisture retention and possible resulting microorganism growth.

C. Examples of metered-dose inhalers, spacer, and dry powder inhaler.

What the public considers an inhaler is technically called a handheld, metered-dose inhaler (MDI). Unfortunately, the MDI is often used incorrectly (Price et al., 2017), and the correct dose of medication is not delivered. For better medication delivery, use a spacer whenever administering medication via an MDI, particularly with a child. Refer to Guidelines for Nursing Care 30-8: Using an Inhaled Medication Device.

Dry powder inhalers (DPIs) are another type of delivery method for inhaled medications. The medication is supplied in a powder form, either in a small capsule or disk inserted into the DPI, or in a compartment inside the DPI. DPIs are breath activated. A quick breath by the patient activates the flow of medication, eliminating the need to coordinate activating the inhaler (spraying the medicine) while inhaling the medicine at the same time. However, the drug output and size distribution of the aerosol from a DPI is more or less dependent on the flow rate through the device, thus the patient must be able to take a powerful, deep inspiration (Alismail et al., 2016; Price et al., 2017). Many types of DPIs are available, with distinctive operating instructions. Some have to be loaded with a dose of medication each time they are used and some hold a preloaded number of doses (referred to as a *diskus* in some cases). It is important to understand the particular instructions for the medication and particular delivery device being used. Refer to the Guidelines for Nursing Care 30-8.

Documenting Medication Administration

The medication administration record is a legal document. Recording each dose of medication as soon as possible after it is given provides a documented record that can be consulted if there are any questions about whether the patient received the medication. Do not record medications before they are given. If something changed and the medication was not actually given, the medication record would incorrectly show that the patient received the medication. Different forms are used for recording medications; an example of an eMAR is given in Figure 30-18.

The name of the medication, dosage, route of administration, time given, and name of the person administering the medication are noted in the record. Record the site used for an injection, the location of a topical or transdermal application, and the naris, eye, or ear used for those administrations. The identity of the nurse completing the documentation is recorded based on the unique user ID and password assigned to each nurse when an eMAR is used. Other specific patient information may be required. For instance, record the pulse rate when administering some cardiac drugs, or record a description of the effects on the patient's pain when administering analgesics.

OMITTED DRUGS

Drugs may be omitted intentionally or inadvertently. The omission and the reason for it are documented on the patient's record. The nurse should notify and collaborate with the prescribing provider regarding the planned or actual omission of drugs. Drugs may be omitted intentionally for the following reasons:

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

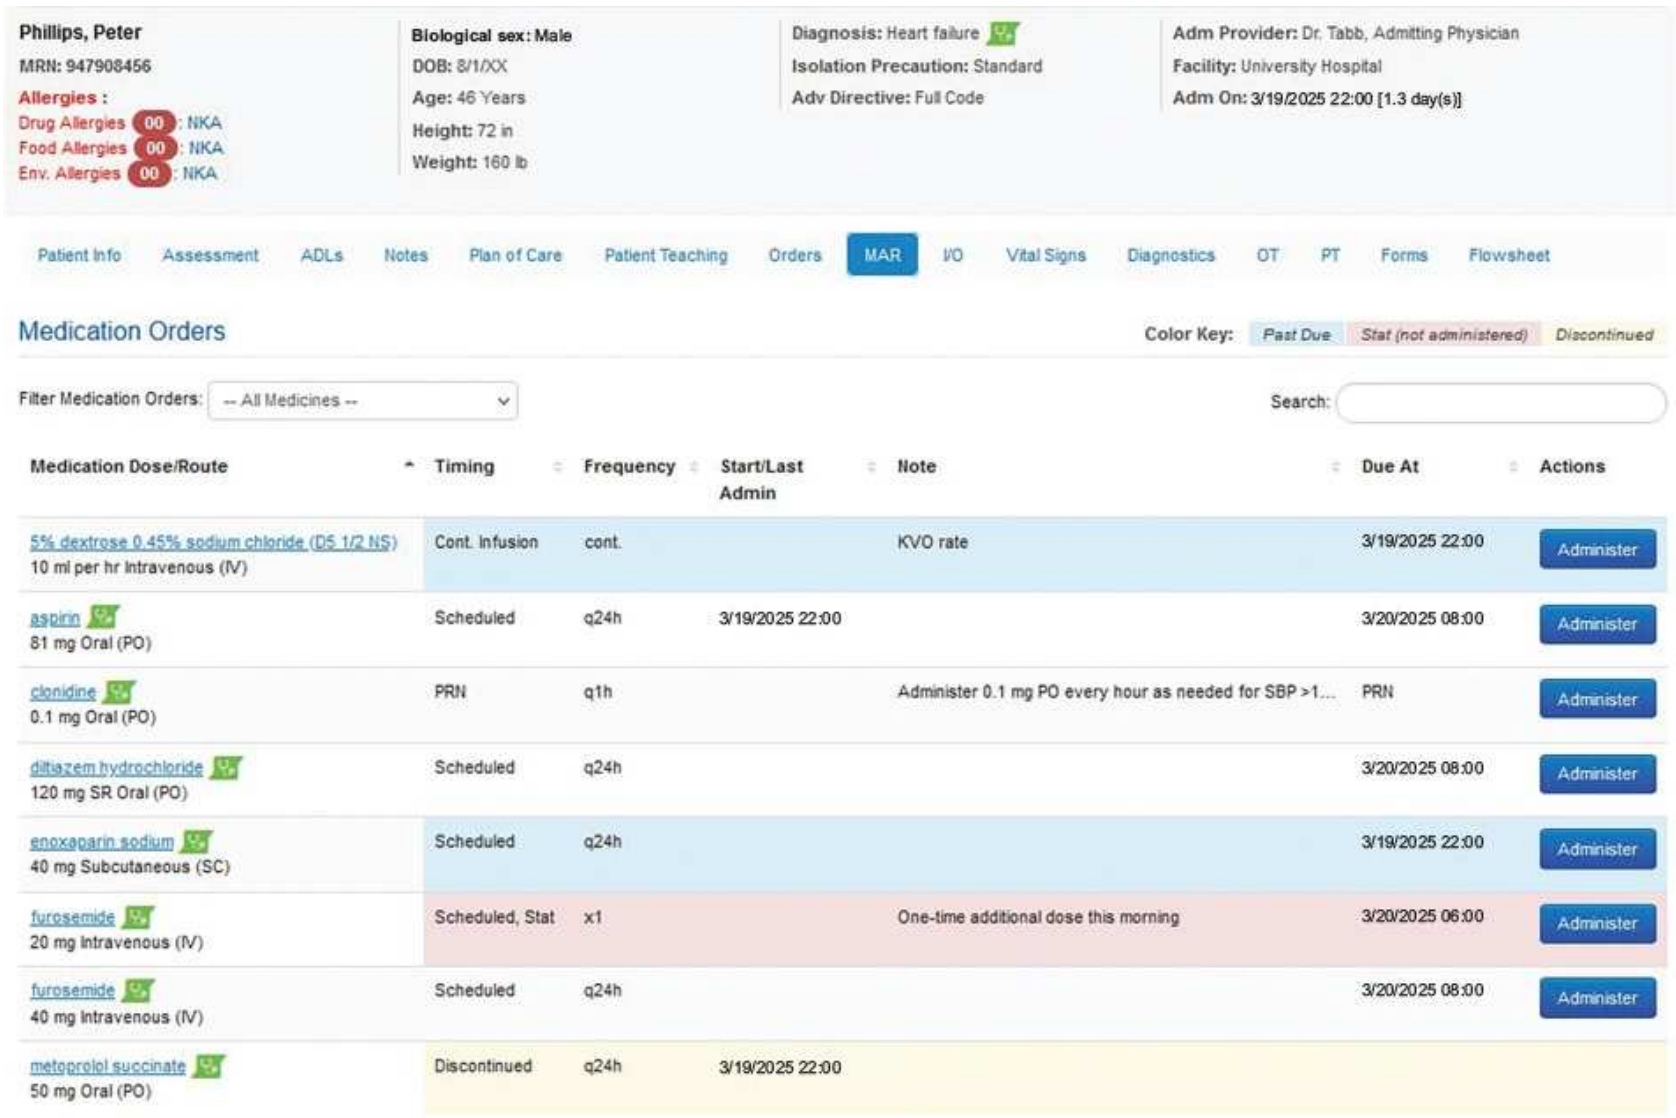


FIGURE 30-18. Example from a web-based academic EHR simulation program.

- The patient is to have a diagnostic test and is required to fast before the test. Oral drugs may be omitted, or their administration may be delayed, depending on the provider's orders.
- The problem for which the medication is intended no longer exists. For example, a laxative has been ordered for a patient. The patient has had a bowel movement and no longer needs the laxative. The laxative is then omitted.
- The medication does not meet prescribed administration guidelines or the clinical judgment of the nurse necessitates follow up with the prescribing provider. For example, it is standard practice to hold certain cardiac drugs if the heart rate or blood pressure fall below a certain level; these parameters may or may not be included with the order itself.
- The patient is suspected of having an allergy to the medication. Any suspected allergy should be reported to the primary care provider.

REFUSED DRUGS

If the patient refuses to take a drug that is considered essential to the therapeutic regimen, report this promptly. It is important to determine the reason for the refusal and to ensure the refusal is not related to a knowledge deficit. If the patient is not persuaded by reasonable efforts and adamantly refuses to take a medication, it is unwise to continue urging the patient. Patients have the right to refuse therapy; recognize and respect that right. Describe the refusal to take prescribed drugs and the manner in which the situation was managed in the patient's record, then report the refusal to pharmacy and the prescribing provider according to facility policy.

Preventing and Responding to Medication Errors

Nurses should take every precaution to avoid errors when administering therapeutic agents. The safe nurse does not allow automatic habits of preparing medications or technology to replace constant thinking, purposeful action, and repeated checking for accuracy. It is important to make use of appropriate resources, including medication software, online medication databases, and consultation with a pharmacist (Choi & Kim, 2019; Fernandes et al., 2020).

Common types of medication errors include the following:

- Inappropriate prescribing of the drug (e.g., incorrect dose, quantity, or route; or inadequate instruction)
- Extra, omitted, or wrong doses
- Administration of a medication to a patient that was not ordered for that patient (see Focused Critical Thinking Guide 30-1)
- Administration of a drug by an incorrect route or at an incorrect rate
- Failure to give a medication within the prescribed time interval
- Incorrect preparation of a drug before administration
- Improper technique when administering a drug

- Giving a drug that has deteriorated

Medication errors often occur at points of transition in care: on admission to a hospital, during the transfer from one department to another, and at discharge home or to another facility. The principal cause of medication error at these times is the incorrect or incomplete transfer of medication information (Barnsteiner, 2008). Nurses and other health care providers must be vigilant in order to minimize the high risk for harm from adverse drug events. A medication reconciliation process that maintains a current, accurate list of medications a patient has received has been shown to decrease the incidence of medication errors that occur at these points of transition in patient care (Barnsteiner, 2008; The Joint Commission, 2020a). Nurses are often responsible for management of these lists and need to be on heightened alert to watch for errors at these points of transition.

Prompt acknowledgment of errors may minimize their possible detrimental effect. The immediate priority is the safety of the patient. The following steps are recommended when a medication error occurs:

1. Check the patient's condition immediately when the error is noted. Observe for the development of adverse effects related to the error.
2. Notify the nurse manager and the primary care provider to discuss possible courses of action, depending on the patient's condition.
3. Report the incident using whatever method is appropriate for your institution. These may include an incident report, a quality-assurance report, a risk assessment/root cause analysis report, or a variance report. These forms—generally called *special event*, *event*, or *unusual occurrence reports*—require an objective, complete account of the medication error. Include the steps taken after the error was recognized. For legal reasons, describe the error fully and accurately. Medication errors are a common allegation in nursing liability cases. Do not document in the patient's record the fact that an incident report was filed. Your institution is bound by state and national mandates to report certain incidents. Some of this reporting is voluntary and some is required. For example, reporting *near-miss* medication errors, where an error almost occurred, is voluntary in some instances, but *sentinel events*, where serious patient harm or death results from the error, require reporting (Wolf & Hughes, 2008; The Joint Commission, 2020b).

There are several voluntary external reporting programs that track medication errors. Nurses and other health care providers are encouraged to report medication errors to these organizations. Reporting errors to one of these programs assists in learning more about patient safety, enhancing patient safety standards, and implementing practices to reduce errors. MEDWATCH (www.fda.gov/Safety/MedWatch/default.htm) is administered by the FDA. The National Coordinating Council for Medication Error Reporting and Prevention (www.nccmerp.org) is a cooperative effort supported by organizations from a wide variety of backgrounds, including consumer, health system, trade and manufacturer, nursing, pharmacy, and medicine organizations, as well as government, licensing, and risk management facilities.

Although event reports often have a negative connotation for many nurses, event reports can provide vital information that can be used to prevent the error from being repeated. These processes and associated tools can provide tracking of errors throughout the institution, providing information that may prevent future medication errors. The emphasis should be on the collaborative efforts necessary to provide safe patient care and decrease the incidence of errors. Peer review committees have proved effective in some health care settings.

Another effort to prevent medication errors involves the assignment of pharmacists to patient care areas in the hospital. The pharmacists spend time on the units and interact directly with the nurses, physicians, and other health care providers to ensure safe medication delivery. They review patient profiles, discuss adverse effects of drugs and potential drug interactions, and ensure that medications are administered at appropriate times across nursing shifts. This team approach has the potential to reduce medication errors significantly.

The health information technologies discussed previously—including computerized health records, computerized provider order entry (CPOE), bar coding, automated drug-dispensing systems, and unit dosing—can potentially contribute to reducing medication errors. However, the person administering the medication, the nurse, needs to remain vigilant in preventing errors.

30-1 Focused Critical Thinking Guide

Medications

You are caring for two residents in a long-term care facility. One of your residents is scheduled to receive a B_{12} injection, and because it will be your first intramuscular injection, it has you more than a little apprehensive. You are eagerly waiting for the moment when your instructor will be free to supervise your injection. Meanwhile, she has cleared you to administer the 1000 meds; you bring a multivitamin, a diuretic, and an antiinflammatory agent to one of your assigned residents. When you go to record the medications you administered, you suddenly realize that

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

you gave them to the wrong resident. When you grab your peer and confide your error, she says, "Whatever you do, don't tell Miss McMullen (the clinical instructor). She gets spastic about med errors and has a reputation for gleefully failing students!" You remember that the resident who received the wrong medications has no known drug allergies and you think that she probably wouldn't suffer any adverse effects from the meds she received. What should you do?

1. Identify goal of thinking

Determine how you ought to respond to the realization that you administered medications to the wrong resident.

2. Assess adequacy of knowledge

Pertinent circumstances: A resident has received three medications that were not prescribed for her. *You are a nursing student in your first clinical rotation* and fear your clinical instructor's response should you inform her about your error. You are unsure of the harm that might result from the resident receiving the wrong medication.

Prerequisite knowledge: To decide how you should respond in this situation, you need to understand your professional obligations, which include your moral and legal accountability for having committed a medication error. You will need knowledge of the pharmacologic action of each of the medications you administered and their potential adverse effects on the resident who received them (possible interactions with other medications she is receiving, contraindications with related adverse effects, etc.). You recognize that there is no way for you to get the knowledge you need to make a morally and legally defensible response unless you admit your error to a responsible party.

Room for error/Time constraints: Because you do not know the effects of these medications, you are not in a position to judge how much room there is for error, nor are you able to make a prudent decision about how much time you have to act. The only defensible response is to seek help to clarify your position immediately because a resident's well-being is potentially at stake. No imagined personal costs would justify a delay in your admission of your error.

3. Address potential problems

The most serious obstacle to critical thinking in this situation would be an inability to think rationally about your obligation to report the error because of your fear of being censured by your clinical instructor. You will want to examine critically your friend's claim that your instructor will respond harshly because this may not, in fact, be the case. You will also want to test your peer's unstated assumption that your primary obligation in this sort of situation is to take care of yourself—even if this course of action results in harm to a patient. It would be helpful to think through the consequences of every health care professional behaving in this manner.

4. Consult helpful resources

Given that you are new to medication administration and are unable to assess the potential harm caused to the resident who received the wrong medications, you will find that your most helpful resource is your instructor, and you will need to enlist her assistance immediately. She will need to contact the resident's health care provider to determine whether there are any contraindications to this resident receiving the medications you administered or possible interactions with other medications. A pharmacist may also need to be consulted. You will want to be familiar with the institution's policy on medication errors and will need to know how to complete an incident report. If the long-term care facility has a risk manager, you may want to consult that person.

5. Critique judgment/decision

You have two options here: Admit your error and initiate appropriate follow-up or attempt to cover up your error and "hope for the best." Your decision will be made on the strength of your moral conviction that your primary obligation is to safeguard patient well-being, even if this involves some self-sacrifice. Once you recognize the potentially disastrous consequences of patients not being able to trust health care professionals to act in their best interests, you decide that there really is only one professionally acceptable response in this situation, and you inform your instructor. It turns out that the resident who received the wrong medications suffered no adverse reactions. You, on the other hand, spend an awful morning following up on your error and even have to delegate your B_{12} injection to another student while you are admitting your error to the resident, her attending, and the charge nurse, as well as completing the special event report. At the end of the day, your instructor compliments you for your honesty and sense of responsibility and cautions you not to repeat the mistake. You are grateful that your worst fears (*failing*) weren't confirmed and leave the unit having learned a powerful lesson about the costs of being accountable.

Teaching about Medications

Teaching about medications is an ongoing process and should begin as soon as the patient is admitted to the health

care facility. Developing a plan of care related to medications is an important part of nursing care. See the Nursing Care plan 30-1 for Regina Sauder on pages 968–969. In many cases, patients continue a prescribed medication regimen at home after discharge from the hospital. Education about prescribed medications influences the patient's adherence to the medication regimen at home. Teaching should be tailored to the patient's level of understanding and with an awareness of any cultural implications. Written instructions, based on an assessment of the patient's level of health literacy, can be used as a reference for the patient. Well-educated patients can act as a final safety net in the medication process when nurses encourage patient participation and use the patient's knowledge in the verification process through informal and formal processes (Garfield et al., 2016; Wang et al., 2019). Refer to Teaching Tips 30-1: Medications.

Explain the techniques of medication administration to the patient and caregivers. Before being discharged from a health care facility, the patient should practice the necessary techniques under the supervision of a nurse to acquire sufficient skill for safe administration. Many patients have learned to give themselves injections, as well as many other medications, when the teaching was planned well and the patient was able and willing to learn. A teach-back that includes a return demonstration provides valuable information regarding gaps in the patient's knowledge, skills, or attitudes.

Emphasize the importance of taking medications as prescribed and for as long as prescribed. A common error made by patients is simply omitting a drug, either through carelessness or because they believe that missing a dose is not important. Various aids are available to remind the patient to take medication on schedule. Medication containers that beep when a dose is due to be taken, scratch-off dots on a medication label, and an electronic cap that signals dosage time and records each time the cap is removed are available. Various smart phone applications (apps) and telehealth-related products are also making their way onto the market. Advise patients to keep their medications with them when they travel. If luggage is lost or misplaced, refilling the prescription may be difficult. Instruct the patient not to alter the dosage without consulting the primary care provider. Also, teach the patient not to discontinue medications when symptoms disappear. Drugs used to maintain health, such as those used to control high blood pressure, need to be continued as prescribed to avoid recurrence of symptoms. Medications such as antibiotics need to be taken as prescribed in their entirety to ensure maximal effect and minimize recurrence.

Teaching Tips 30-1

MEDICATIONS

Health Topic	Teaching Tip	Why Is This Important?
General information	• Medication name and dosage • Intended effects of medication • Expected side effects of medication	Patients should know the names and reasons for medications in case of medical emergencies. Patients should also know expected side effects of the medication so they do not stop taking the medication.
Taking the medication	• Medications should be taken at the same time every day. • Teach whether food, beverages, or other medications have any effect on the medication. • Teach what patient should do if a dose is missed. • Teach patient to take medications as prescribed for as long as prescribed. • Teach not to alter drug dosage without consulting health care provider.	If patients make taking medications a part of their daily routine, they are less likely to miss a dose. Some medications require food to prevent stomach irritation; absorption of other medications is impeded by food in the stomach. Patients are likely to miss a dose of medication and need to know what to do if this happens. Some medications have severe consequences if stopped abruptly; others need to be taken for a set period of time and at a recommended dosage to be effective.
Special instructions	• Teach what to do when adverse effects occur. • Keep medications with them when traveling.	Patients need to know whom to contact if any adverse effects occur. Luggage can be lost or

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Do not share medications with other people.
- Store properly.
- Keep a list of all medications, including OTC drugs, dietary supplements, herbs, and natural supplements.

misplaced. Teach patients that just because someone else has similar symptoms, it does not mean that the same medication should be taken. Medication should be kept out of the reach of children and pets. For labeling purposes, medications should be kept in the container in which they were dispensed. Some medications are sensitive to humidity and light; keep medications in a cool, dry place. Keep your health care providers up to date on your list of medications.

Nursing Advocacy in Action

Substance use disorder during pregnancy results in significant health problems for the pregnant person, fetus, and newborn. Recently, OxyContin has become a popular alternative to other street drugs such as heroin. In utero exposure to opiates is associated with neonatal abstinence syndrome in as many as 55% to 94% of exposed infants. The onset and severity of the infant's withdrawal from the drug varies with the type and duration of the drug taken by the pregnant person (Hudak et al., 2016).

PATIENT SCENARIO

Jasmine is a 24-year-old single mother who is experiencing homelessness. She has a history of injecting OxyContin (120 to 500 mg/day) intravenously for the past 2 years due to pain in her back. She has a history of barbiturate abuse during her last pregnancy. She has delivered two other infants prematurely at 32 weeks and 36 weeks. Both of these children are in foster care.

IMPLICATIONS FOR NURSING ADVOCACY

How will you respond if you are Jasmine's clinic nurse? Talk with your classmates and experienced nurses about the questions that follow.

- If you elect to advocate for Jasmine and her baby, what practical steps can you take to ensure better health outcomes?
- Who is your priority in this situation: Jasmine or the baby?
- How do we handle a situation where the needs of the individual may not be readily met by the resources available? Discuss potential/actual health disparities for Jasmine who is experiencing homelessness.
- What is reasonable to expect of a student nurse, a graduate nurse, and an experienced nurse in this situation?
- What advocacy skills are needed to effectively respond to this challenge?

Caution the patient not to share prescribed medications with other family members, friends, or neighbors. Inappropriate use of another person's drugs (diversion) can have serious consequences.

At the very least, a patient should be able to verbalize the following:

- How and when to administer the medication
- When to notify the health care provider
- Expected side effects and potential adverse effects

Nurses have a responsibility to teach about substance use disorder. Teaching may take place on an individual basis or on a family or community level. Substance use disorder is a major public health concern worldwide, especially among teenagers and young adults. Refer to the Nursing Advocacy in Action box. Continued public and individual education is indicated, and nurses are also expected to set high standards for their own behavior and use of drugs. Because substance use disorder is increasingly common in health care providers, nurses who suspect that a colleague is abusing drugs must observe, document, and intervene for the patients' safety.

Promoting Health 30-1

MEDICATIONS

Use the assessment checklist to determine how well you are meeting your needs related to safe medication practices. Then develop a prescription for self-care by choosing appropriate behaviors from the list of suggestions.

Assessment Checklist

☐ almost always ☐ sometimes ☐ almost never

☐ ☐ ☐ 1. I store medications in a safe place (e.g., a cool, dry place, away from direct sunlight, out of the reach of children).

☐ ☐ ☐ 2. I discard medications that have passed their expiration date.

☐ ☐ ☐ 3. I wear a Medic-Alert tag or carry information that identifies a drug allergy or required medication.

☐ ☐ ☐ 4. I am cautious about combining prescribed medication with OTC drugs, herbal supplements, alcohol, or foods that can interact with the drug.

Self-Care Behaviors

1. Finish all prescriptions as ordered by your provider.
2. Avoid foods, alcohol, or over-the-counter drugs and herbal supplements that may interact with a prescribed drug.
3. Use available resources (textbooks, pharmacist, provider) to verify the potential for drug interactions or possible adverse effects of a medication.
4. Use a reminder system to maintain medication schedule.
5. Avoid sharing medications or taking someone else's prescribed pills.
6. Complete any laboratory tests necessary for maintenance or adjustment of a medication regimen.
7. Practice safe behaviors when storing medications.
8. Purchase drugs from the same pharmacy as an additional safeguard with multiple medication regimens.

Information to promote safe medication practices, such as information about prescription and over-the-counter medications, medication safety, medication administration, and alternative medications, is available online.

Nurses working with patients to promote appropriate behaviors related to medication administration should examine their own behaviors as factors in the success of the plan. Nurses who role model good health behaviors are more effective teachers. Use the display, Promoting Health 30-1: Medications, for yourself before using it with others.

Evaluating

Assess the effectiveness of drugs in several ways. Clinical observation is the first method. Collect subjective data from the patient (e.g., "My pain has disappeared.") and collect objective data (e.g., the patient's vital signs) to evaluate effectiveness of the medication. It is also important to assess the patient for adverse drug effects.

Measurement of drug levels in body fluids provides data about the patient's response to a particular medication. For many drugs—including digoxin, warfarin, anticonvulsants, and aminoglycoside antibiotics—monitoring blood levels is an important component of therapy (Frandsen & Pennington, 2021; McCuistion et al., 2021). Test the patient to determine whether the drug level in the blood is within the therapeutic range. Drug dosages may be adjusted based on the serum drug level. Monitoring systems can also assist the nurse in evaluating drug effectiveness. For the patient with an arrhythmia, for example, a cardiac monitor can show a change in heart rhythm.

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the object of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop your expertise in evaluating the plan of care, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following:

- How aware are you of the importance of the checks and rights in guiding your medication administration practices?

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Are you able to integrate your knowledge of medications into your patient teaching?

- What value do you attach to involving the patient in medication safety practices in the hospital, in the community, and in their homes? How do you individualize the care for patients when so many guidelines, policies, and procedures dictate your care?
- What plan do you have to stay abreast of evolving national guidelines and goals related to safe medication administration?

Keeping up with the latest evidence-based practice guidelines can be challenging. Global shifts and evolving statistics change the emphasis of our nursing care. Balancing the needs of your individual patient with these responsibilities requires mindfulness and intentionality.

Perhaps the most important questions to reflect on are: Are your patients and families/caregivers better for having had *you* share in the critical responsibility of partnering with them to ensure appropriate and safe medication administration practices? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Nursing Care Plan for *Regina Sauder 30-1*

Regina Sauder, 73 years old, presented to the emergency department with pain, swelling, and erythema of her left calf. She has a history of lymphoma. Vascular studies of the lower extremities show a left leg deep vein thrombosis. She was admitted to the hospital and started on intravenous heparin. After 3 days of heparin therapy, she was started on warfarin, in addition to the heparin. Her warfarin dose is being adjusted based on her daily INR level. Daily assessment of her INR level will continue in the hospital until her level is therapeutic. Initially, weekly monitoring of the INR level will continue after discharge.

ASSESSMENT FINDINGS

- PTT is 60 seconds, within expected parameters for adequate hypercoagulation with heparin therapy.
- INR is 1.2, on the low end of expected parameter for adequate hypercoagulation with warfarin therapy.
- Patient's left lower leg is without swelling, tenderness, and erythema.
- Patient states, "It feels so much better. I had so much pain, but not now. But, why am I taking two different medications? Am I going to have to go home with this tube in my arm?" Mrs. Sauder appears anxious, is fidgeting, and becomes tearful during the conversation with the nurse. She states, "I think this new pill sounds scary." Her husband reports unease about his wife's ability "to keep track of everything."
- Patient and husband unable to verbalize knowledge regarding signs of bleeding, dosage, timing of administration, dietary guidelines, or need for scheduled follow-up blood work.
- Patient and her husband live in a two-story home, with the bathroom on the second floor.

HEALTH PROBLEM

Bleeding risk due to warfarin administration

EXPECTED OUTCOME

By 3/20/24 the patient and her husband will:

- Identify signs and symptoms of bleeding

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT

Provide instruction identifying signs and symptoms of bleeding.	Focuses teaching session on a single idea, allowing the patient to concentrate more completely on the material. Older adults and highly anxious patients may have reduced short-term memory and benefit from mastery of one concept at a time.	3/19/24 Outcome met. Mrs. Sauder and her husband are able to identify signs and symptoms of bleeding to report to their health care provider. *B. Huber, RN*
Give patient and husband written pamphlet from drug manufacturer.	Provide information using various media because different people take in information in different ways. Provides concrete reinforcement.	
Encourage questions.	Patients and family members often feel shy or embarrassed about asking questions. Gives permission to ask.	

EXPECTED OUTCOME

By 3/20/24 the patient's husband will:

- Remove from their home potential hazards that could lead to falls and subsequent bleeding.

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Review with patient and husband potential causes of falls at home.	Falls may cause internal bleeding.	3/18/24 Outcome met. Husband removed several loose rugs, repaired loose stairs, and improved the lighting at the stairs to the bathroom. *B. Clapp, RN*
Assist the patient and husband in evaluating their home environment to identify potential hazards.	Remove potential hazards to prevent falls and injury.	
Encourage the use of proper lighting, handrails on stairways, removal of small rugs, fastening loose carpet edges.	Remove potential hazards to prevent falls and injury.	

SAMPLE DOCUMENTATION

3/17/204 Nursing

Patient, husband, and nurse met to discuss potential effects of warfarin therapy and risk for injury. Discussion centered on importance of preventing injury while on warfarin at home. See care plan. Patient progress will be evaluated in 4 days, 3/21/24.

B. Clapp, RN

Skill 30-1 Administering Oral Medications

DELEGATION CONSIDERATIONS

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

The administration of oral medications is not delegated to assistive personnel (AP). The administration of specified oral medications to stable patients in some long-term care settings may be delegated to AP who have received appropriate training. Depending on the state's nurse practice act and the organization's policies and procedures, the administration of oral medications may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Medication in disposable cup or oral syringe
- Liquid (e.g., water, juice) with straw, if not contraindicated
- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)
- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in place. Clarify any inconsistencies. Check the patient's health record for allergies.	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy located in a health care facility and to outpatient pharmacies.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and potential adverse effects of the medications to be administered. Consider the appropriateness of the medication for this patient.	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication.
 3. Perform hand hygiene.	Hand hygiene prevents the spread of microorganisms.
4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode into the computer and scan employee identification, if required.	Locking the medication supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized users into the computer system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.
7. Read the eMAR/MAR and read the label when selecting the proper medication from the medication supply system or patient's medication drawer.	This is the *first* check of the medication label.
8. Read the label and compare the medication label with the eMAR/MAR (Figure 1). Check expiration dates and perform calculations, if necessary. Scan the bar code on the package, if required.	This is the *second* check of the label. Verify calculations with another nurse to ensure safety, if necessary.

FIGURE 1. Comparing medication label with eMAR.

9. Prepare the required medications:

   a. *Unit dose packages:* **Do not open the wrapper until at the bedside.** Keep opioids and medications that require special nursing assessments separate from other medication packages.

   Wrapper is kept intact because the label is needed for an additional safety check. Special assessments may be required before giving certain medications. These may include assessing vital signs and checking laboratory test results.

   b. *Multidose containers:* When removing tablets or capsules from a multidose bottle, pour the necessary number into the bottle cap and then place the tablets or capsules in a medication cup. Break only scored tablets, if necessary, to obtain the proper dosage. Do not touch tablets or capsules with your hands.

   Pouring medication into the cap allows for easy return of excess medication to the bottle. Pouring tablets or capsules into your hand is unsanitary.

   c. *Liquid medication in multidose bottle:* When pouring liquid medications out of a multidose bottle, hold the bottle so the label is against the palm. Use the appropriate measuring device when pouring liquids and read the amount of medication at the bottom of the meniscus at eye level (Figure 2). Wipe the lip of the bottle with a paper towel.

   Liquid that may drip onto the label makes the label difficult to read. Accuracy is possible when the appropriate measuring device is used and then read accurately.

FIGURE 2. Measuring at eye level. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

10. **Depending on facility policy, the third check of the label may occur at this point. If so, when all medications for one patient have been prepared, read the label and recheck the labels with the eMAR/MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**

    This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the third check to occur at the bedside, after identifying the patient and before administration.

11. Replace any multidose containers in the patient's drawer or medication supply system. **Log out of**

    Locking the medication supply system or drawer safeguards the patient's medication supply. Facility

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and/or lock the medication supply system before leaving it.	accrediting organizations require medication supply systems to be locked when not in use.
12. Transport medications to the patient's bedside carefully and keep the medications in sight at all times.	Careful handling and close observation prevent accidental or deliberate disarrangement of medications.
13. **Ensure that the patient receives the medications at the correct time.**	Check facility policy, which may allow for administration within a period of 30 minutes before or 30 minutes after the designated time.
 14. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 15. **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two of the following methods** (The Joint Commission, 2021):	Identifying the patient ensures the right patient receives the medications and helps prevent errors. The patient's room number or physical location is not used as an identifier (The Joint Commission, 2021). Replace the identification band if it is missing or inaccurate in any way.
a. Check the name on the patient's identification band (Figure 3).	
b. Check the identification number on the patient's identification band.	
c. Check the birth date on the patient's identification band.	
d. Ask the patient to state their name and birth date, based on facility policy.	This requires a response from the patient, but illness and strange surroundings often cause patients to be confused.
16. **Complete necessary assessments before administering medications. Check the patient's allergy bracelet, if present, or ask the patient about allergies. Explain the purpose and action of each medication to the patient.**	Assessment is a prerequisite to administration of medications.
17. Scan the patient's bar code on the identification band, if required (Figure 4) (The Joint Commission, 2021).	The bar code provides an additional check to ensure that the medication is given to the right patient.

FIGURE 3. Comparing patient's name and identification number with eMAR.

FIGURE 4. Scanning bar code on patient's identification bracelet. (*Photo by B. Proud.*)

18. **Based on facility policy, the third check of the medication label may occur at this point. If so, read the label and recheck the label with the eMAR/MAR before administering the medications to the patient.**	Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration. If facility policy directs the *third* check at this time, this *third* check ensures accuracy and helps prevent errors.
19. Assist the patient to an upright or lateral (side-	Swallowing is facilitated by proper positioning. An

lying) position.	upright or side-lying position protects the patient from aspiration.
20. Administer medications:	
a. Offer water or other permitted fluids with pills, capsules, tablets, and some liquid medications.	Liquids facilitate swallowing of solid drugs. Some liquid drugs are intended to adhere to the pharyngeal area, in which case liquid is not offered with the medication.
b. Ask whether the patient prefers to take the medications by hand or in a cup.	This encourages the patient's participation in taking the medications.
21. **Remain with the patient until each medication is swallowed. Never leave medication at the patient's bedside** (Figure 5).	Unless you have seen the patient swallow the drug, the drug cannot be recorded as administered. The patient's health record is a legal record. Medications can be left at the bedside only with a prescriber's order.

FIGURE 5. Remaining with patient until each medication is swallowed.

22. Assist the patient to a comfortable position. Remove PPE, if used. Perform hand hygiene.	Promotes patient comfort. Proper removal of PPE prevents transmission of microorganisms. Hand hygiene deters the spread of microorganisms.
23. Document the administration of the medication immediately after administration. See Documentation section below.	Timely documentation helps to ensure patient safety.
24. Evaluate the patient's response to the medication within the appropriate time frame.	The patient needs to be evaluated for therapeutic and adverse effects from the medication.

DOCUMENTATION

Guidelines

Record each medication immediately after it is administered on the eMAR/MAR or health record using the required format. Include the date and time of administration (Figure 6). If using a bar-code system, medication administration is automatically recorded when the bar code is scanned. PRN medications require documentation of the reason for administration. Prompt recording avoids the possibility of accidentally repeating the administration of the drug. If the drug was refused or omitted, record this in the appropriate area on the medication record and notify the health care team as appropriate. This verifies the reason medication was omitted and ensures that health care personnel providing care for the patient are aware of the occurrence. Recording administration of an opioid may require additional documentation on a controlled-substance record, stating drug count and other specific information. A record of fluid intake and output measurement is required.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 6. Recording each medication administered on eMAR.

Sample Documentation

Practice documenting medication administration in *Lippincott DocuCare*.

8/6/25 0835 Patient states he is having constant stabbing leg pains. Rates pain as an 8/10. Percocet 2 tabs administered.

—*K. Sanders, RN*

8/6/25 0905 Patient resting comfortably. Rates leg pain as a 1/10.

—*K. Sanders, RN*

8/6/25 1300 Patient states he does not want pain medication, despite return of leg pain. States, "It made me feel woozy last time." Feelings discussed with patient. Patient agrees to take Percocet 1 tab at this time.

—*K. Sanders, RN*

8/6/25 1320 Percocet, 1 tablet given PO.

—*K. Sanders, RN*

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient states that it feels like medication is lodged in throat:* Offer the patient more fluids to drink. If allowed, offer the patient bread or crackers to help move the medication to the stomach.
- *It is unclear whether the patient swallowed the medication:* Check in the patient's mouth, under their tongue, and between their cheek and gum. Patients with altered cognition may not be aware that the medication was not swallowed. Also, patients may "cheek" medications to avoid taking the medication or to save it for later use.
- *Patient vomits immediately or shortly after receiving oral medication:* Assess vomit, looking for pills or fragments. Do not readminister the medication without notifying the health care team. If a whole pill is seen and can be identified, the prescriber may ask that the medication be administered again. If a pill is not seen or medications cannot be identified, do not readminister the medication in order to prevent the patient from receiving too large a dose.
- *Child refuses to take oral medications:* Some medications may be mixed in a small amount of food, such as pudding or ice cream. Do not add the medication to liquids because the medication may alter the taste of liquids; if the child then refuses to drink the rest of the liquid, you will not know how much of the medication was ingested. Use creativity when devising ways to administer medications to a child. See the section below, Infant and Child Considerations, for suggestions.
- *Capsule or tablet falls to the floor during administration:* Discard and obtain a new dose for administration. This prevents contamination and transmission of microorganisms.
- *Patient refuses medication:* Explore the reason for the patient's refusal. Review the rationale for use of the drug, explain the risk of refusal, and any other information that may be appropriate. If you are unable to administer the medication despite education and discussion, document the omission and any education and/or explanation provided related to attempts to facilitate administration according to facility policy. The health care team should be informed of the refusal, especially when the omission poses a specific threat to the patient (McCuistion et al., 2021).

SPECIAL CONSIDERATIONS

General Considerations

- Some liquid medication preparations, such as suspensions and emulsions, require agitation to ensure even distribution of medication in the solution. Be familiar with the specific requirements for medications you are administering.
- Place medications intended for sublingual absorption under the patient's tongue. Instruct the patient to allow the medication to dissolve completely. Reinforce the importance of not swallowing the medication tablet.
- Some oral medications are provided in powdered forms. Verify the correct liquid in which to dissolve the medication for administration. This information is usually included on the package. Verify any unclear instructions with a pharmacist or medication reference. If there is more than one possible liquid in which to dissolve the medication, include the patient in the decision process; patients may find one choice more palatable than another.
- Ongoing assessment is an important part of nursing care for both evaluation of patient response to administered medications and early detection of adverse drug reactions. If an adverse effect is suspected, withhold further medication doses and notify the health care team. Additional intervention is based on type of reaction and patient assessment.
- If the patient questions a medication order or states the medication is different from the usual dose, always recheck and clarify with the original prescription and/or prescriber.
- If the patient's level of consciousness is altered or their swallowing is impaired, check with the health care team to clarify the route of administration or alternative forms of medication. This may also be a solution for a pediatric or a confused patient who is refusing to take a medication.
- Patients with poor vision can request large-type labels on medication containers. A magnifying lens also may be helpful.
- Provide written medication information to reinforce discussion and education in the appropriate language, if the patient is literate. If the patient is unable to read, provide written information to family or caregiver, if appropriate. Written information should be at a 4th- to 6th-grade level, using short sentences and simple words, and incorporate pictures to increase ease of understanding (Patient Safety Network, 2019).
- If the patient has difficulty swallowing tablets, it may be appropriate to crush the medication to facilitate administration. Not all medications can be crushed or altered; long-acting and slow-release drugs are examples of medications that cannot be crushed. Check manufacturer's recommendations and/or with a pharmacist to verify (Anderson, 2019; Boullata, 2021; White & Bradnam, 2015).
- If the medication can be crushed, use a pill-crusher or mortar and pestle to grind the tablet into a powder. Crush each pill one at a time. Dissolve the powder with water or other recommended liquid in a liquid medication cup, keeping each medication separate from the others. Keep the package label with the medication cup for future comparison of information. Combine the crushed medication with a small amount of soft food, such as applesauce or pudding, to facilitate administration.
- Liquid medication not dispensed as unit dose should be administered in an oral syringe when available (ISMP, 2020) (Figure 7).

FIGURE 7. Monoject™ oral syringe. Note that specific syringes are designed for "ORAL USE ONLY." (Courtesy and © Becton, Dickinson and Company. Reprinted with permission.)

Infant and Child Considerations

- Special devices, such as oral syringes and calibrated nipples, are available in a pharmacy to ensure accurate dose calculations for young children and infants.
- Some creative ways to administer medications to children include the following: have a "tea party" with medicine cups; place a designated oral tip syringe or dropper in the space between the cheek and gum and slowly administer

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

the medication (Kyle & Carman, 2021); save a special treat for after the medication administration (e.g., movie, playroom time, or a special food, if allowed).

- If a medication has an objectionable taste, warn the child if they are old enough to understand. Failing to warn the child is likely to decrease the child's trust in the nurse. Do not lie to a child about medication administration.
- Caution caregivers to remove and dispose of plastic syringe caps present on the end of syringes before drug administration to reduce the risk of choking. Companies manufacture syringes labeled "oral use" without the caps on them and should be considered for use (ISMP, 2020).

Older Adult Considerations

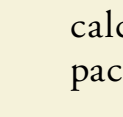
- Older adults with arthritis may have difficulty opening childproof caps. On request, the pharmacist can substitute a cap that is easier to open. A rubber band twisted around the cap may provide a more secure grip for older adults.
- Consider large-print written medication information, when appropriate.
- Physiologic changes associated with the aging process, including decreased gastric motility, muscle mass, acid production, and blood flow, can affect the patient's response to the medication, including drug absorption and increased risk of adverse effects. Older adults are more likely to take multiple drugs. As a result, drug interactions in the older adult are a significant consideration that may affect mental status (Frandsen & Pennington, 2021).

Community-Based Care Considerations

- Encourage the patient to discard expired prescription medications based on label instructions or community guidelines.
- Discuss safe storage of medications when there are children and pets in the home environment.
- Discuss with parents the difference in over-the-counter medications made for infants and medications made for children. Many times, parents do not realize that there are different strengths to the actual medications, leading to under- or overdosing.
- Encourage patients to carry a card listing all medications they take, including dosage and frequency, in case of an emergency.
- Discuss the importance of using an appropriate measuring device for liquid medications. Caution patients not to use eating utensils for measuring medications; use a liquid medication cup, oral syringe, or measuring spoon to provide accurate dosing.

Skill 30-2 Removing Medication From an Ampule

DELEGATION CONSIDERATIONS



The preparation of medication from an ampule is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the preparation of medication from an ampule may be delegated to a licensed practical/vocational nurse (LPN/LVN). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Sterile syringe and filter needle
- New needle for replacing filter needle, if indicated
- Ampule of medication
- Antimicrobial swab
- Small, sterile gauze pad
- Gloves
- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders

place. Clarify any inconsistencies. Check the patient's health record for allergies.	were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy located in a health care facility and to outpatient pharmacies.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and adverse effects of the medications to be administered. Consider the appropriateness of the medication for this patient.	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication.
	Hand hygiene prevents the spread of microorganisms.
3. Perform hand hygiene.	
4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode and scan employee identification, if required.	Locking the medication supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized users into the computer system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.
7. Read the eMAR/MAR and read the label when selecting the proper medication from the medication supply system or the patient's medication drawer.	This is the *first* check of the label.
8. Read the label and compare the label with the eMAR/MAR. Check expiration dates and perform calculations, if necessary. Scan the bar code on the package, if required.	This is the *second* check of the label. Verify calculations with another nurse to ensure safety, if necessary.
9. Tap the stem of the ampule (Figure 1) or twist your wrist quickly (Figure 2) while holding the ampule vertically.	This facilitates movement of medication in the stem to the body of the ampule.
10. Put on gloves. Using the antimicrobial swab, scrub the neck of the ampule. Wrap a small sterile gauze pad around the neck of the ampule.	Gloves reduce risk of injury to hands from glass (Innovation Compounding, 2020). Scrubbing the neck is necessary to reduce the risk of contamination (Dolan et al., 2016; Innovation Compounding, 2020). Wrapping the neck of the ampule with gauze protects your fingers from the glass as the ampule is broken.
11. Breaking away from your body, use a snapping motion to break off the top of the ampule along the scored line at its neck (Figure 3). **Always break away from your body.**	This protects your face and fingers from any shattered glass fragments.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 1. Tapping stem of the ampule.

FIGURE 2. Twisting wrist quickly while holding ampule vertically.

FIGURE 3. Using a snapping motion to break top of ampule.

12. Attach the filter needle to the syringe. Remove the cap from the filter needle by pulling it straight off.	Use of a filter needle prevents the accidental withdrawing of small glass particles with the medication (Innovation Compounding, 2020). Pulling the cap off in a straight manner prevents accidental needlestick.
13. Withdraw the medication in the amount ordered plus a small amount more (approximately 30% more). **Do not inject air into the solution. While inserting the filter needle into the ampule, be careful not to touch the rim.** Use either of the following methods to withdraw the medication:	By withdrawing an additional small amount of medication, any air bubbles in the syringe can be displaced once the syringe is removed while allowing ample medication to remain in the syringe. The contents of the ampule are not under pressure; therefore, air is unnecessary and will cause the contents to overflow. The rim of the ampule is considered contaminated.
a. Insert the tip of the needle into the ampule, which is upright on a flat surface, and withdraw fluid into the syringe (Figure 4). **Touch the plunger only at the knob.**	Handling the plunger only at the knob will keep the shaft of the plunger sterile.
b. Insert the tip of the needle into the ampule and	Surface tension holds the fluids in the ampule when

invert the ampule. Keep the needle centered and not touching the sides of the ampule. Withdraw fluid into the syringe (Figure 5). **Touch the plunger only at the knob.**

FIGURE 4. Withdrawing medication from upright ampule.

inverted. If the needle touches the sides or is removed and then reinserted into the ampule, surface tension is broken, and fluid runs out. Handling the plunger only at the knob will keep the shaft of the plunger sterile.

FIGURE 5. Withdrawing medication from inverted ampule.

14. Wait until the needle has been withdrawn to tap the syringe and expel the air carefully by pushing on the plunger. **Check the amount of medication in the syringe with the medication dose and discard any surplus, according to facility policy.**

    Ejecting air into the solution increases pressure in the ampule and can force the medication to spill out over the ampule. Ampules may have overfill. Careful measurement ensures that the correct dose is withdrawn.

15. **Depending on facility policy, the third check of the label may occur at this point. If so, when all medications for one patient have been prepared, read the label and recheck the labels with the eMAR/MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**

    This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration.

16. Label the syringe with the medication name, dose, and amount (The Joint Commission, 2021).

    Unlabeled syringes are unidentifiable and may lead to a medication administration error (The Joint Commission, 2021).

17. **Engage the safety guard on the filter needle and remove the needle. Discard the filter needle in a suitable container. Attach the appropriate administration device to the syringe.**

    The filter needle used to draw up medication should not be used to administer the medication. This will prevent any glass shards from entering the patient during administration.

18. Discard the ampule in a suitable container. Remove gloves and perform hand hygiene.

    Any medication that has not been removed from the ampule must be discarded because sterility of contents cannot be maintained in an opened ampule. Removing gloves and performing hand hygiene deters the spread of microorganisms

19. **Log out of and/or lock the medication supply**

    Locking the medication supply system safeguards the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

system before leaving it.

patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use.

Hand hygiene deters the spread of microorganisms.

20. Perform hand hygiene.

21. Proceed with administration, based on prescribed route.

See appropriate skill for prescribed route.

DOCUMENTATION

Guidelines

It is not necessary to record the removal of the medication from the ampule. Prompt recording of administration of the medication is required immediately after it is administered.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *You cut yourself while trying to open the ampule:* Discard the ampule and medication in case contamination has occurred. Clean and bandage the wound and obtain a new ampule. Communicate the incident according to facility policy.
- *All of medication was not removed from the stem and insufficient medication remains in body of ampule for dose:* Discard the ampule and drawn medication. Obtain a new ampule and start over. Medication in the original ampule stem is considered contaminated once the neck of the ampule has been placed on a nonsterile surface.
- *You inject air into inverted ampule, spraying medication:* Wash your hands to remove any medication. If any medication has gotten into your eyes, perform eye irrigation. Obtain a new ampule for medication dose. Communicate the incident according to facility policy.
- *Plunger becomes contaminated before inserted into ampule:* Discard the needle and syringe and start over. If the plunger is contaminated after medication is drawn into the syringe, it is not necessary to discard and start over. The contaminated plunger will enter the barrel of the syringe when pushing the medication out, will not come in contact with the medication, and will not contaminate the medication.

SPECIAL CONSIDERATIONS

- When mixing medications in one syringe, preparation of medications in one syringe depends on how the medication is supplied. When preparing medications from an ampule and a vial, prepare the medication in the vial first. Draw up the medication in the ampule *after* the medication in the vial (see Skill 30-3).

Skill 30-3 Removing Medication From a Vial

DELEGATION CONSIDERATIONS

The preparation of medication from a vial is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the preparation of medication from a vial may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Sterile syringe and needle or blunt cannula (size depends on medication being administered)
- Needleless access device (if available)
- Vial of medication
- Antimicrobial swab
- Second needle (optional)

- Filter needle (optional)
- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in place. Clarify any inconsistencies. Check the patient's health record for allergies.	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy located in a health care facility and to outpatient pharmacies.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and adverse effects of the medications to be administered. Consider the appropriateness of the medication for this patient.	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication.
 3. Perform hand hygiene.	Hand hygiene deters the spread of microorganisms.
4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode and scan employee identification, if required.	Locking the medication supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized users into the system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.
7. Read the eMAR/MAR and read the label when selecting the proper medication from the medication supply system or the patient's medication drawer.	This is the *first* check of the label.
8. Read the label and compare the label with the eMAR/MAR. Check expiration dates and perform calculations, if necessary. Scan the bar code on the package, if required.	This is the *second* check of the label. Verify calculations with another nurse to ensure safety, if necessary.
9. Remove the metal or plastic cap on the vial that protects the self-sealing stopper.	The cap needs to be removed to access the medication in the vial.
10. **Scrub the self-sealing stopper top with the antimicrobial swab and allow to dry.**	The antimicrobial swab removes surface microbial contamination. Allowing the antimicrobial solution to dry completely (5 to 20 seconds) ensures complete antimicrobial effectiveness (Gorski et al., 2021; Slater et al., 2018). Drying also prevents antimicrobial solution from entering the vial on the needle.
11. Remove the cap from the needle or blunt cannula by pulling it straight off. **If the vial in use is a multidose vial**, touch the plunger only at the knob and draw back an amount of air into the syringe that is equal to the specific dose of medication to be withdrawn. If the vial in use is a single-use vial, there	Pulling the cap off in a straight manner prevents accidental needlestick injury. Handling the plunger only at the knob will keep the shaft of the plunger sterile. Because a vial is a sealed container, injection of an equal amount of air (before fluid is removed) is required to prevent the formation of a partial

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

is no need to draw air into the syringe.	vacuum. If not enough air is injected, the negative pressure makes it difficult to withdraw the medication after repeated use.
12. Hold the vial on a flat surface. Pierce the self-sealing stopper in the center with the needle tip (Figure 1) or blunt cannula; alternatively, insert a needleless access device (Figure 2) into the stopper on the vial and connect the syringe. Inject the measured air into the space above the solution. **Do not inject air into the solution.** If the vial in use is a single-use vial, there is no need to inject air into the vial.	Air bubbled through the solution could result in withdrawal of an inaccurate amount of medication. Needleless access devices may be used to prevent needlestick injuries based on facility policy (Frandsen & Pennington, 2021).
13. Invert the vial. **Keep the tip of the needle or blunt cannula below the fluid level if in use (Figure 3).**	This prevents air from being aspirated into the syringe.
14. Hold the vial in one hand and use the other to withdraw the medication. **Touch the plunger only at the knob. Draw up the prescribed amount of medication while holding the syringe vertically and at eye level (Figure 4).**	Handling the plunger only at the knob will keep the shaft of the plunger sterile. Holding the syringe at eye level facilitates accurate reading, and the vertical position makes removal of air bubbles from the syringe easy.

FIGURE 1. Injecting air with vial upright.

FIGURE 3. Positioning needle tip in solution.

FIGURE 2. Example of a needleless system to access a medication vial.

FIGURE 4. Withdrawing medication at eye level.

15. If any air bubbles accumulate in the syringe, tap the barrel of the syringe sharply and move the needle past the fluid into the air space to re-inject the air bubble into the vial. Return the needle tip to the solution and continue withdrawal of the medication.	Removal of air bubbles is necessary to ensure an accurate dose of medication.

16. After the correct dose is withdrawn, remove the needle or needleless access device from the vial; carefully replace the sterile cap over the needle if used. Alternatively, carefully attach a needle or syringe cap. Some facilities require changing the needle, if one was used to withdraw the medication, before administering the medication.	Capping prevents contamination and protects against accidental needlesticks. A one-handed recap method may be used as long as care is taken not to contaminate the needle during the process. Changing the needle may be necessary because passing the needle through the stopper on the vial may dull the needle. In addition, it ensures the tip of the needle is free from medication residue, significantly reducing pain intensity associated with the injection (Ağaç & Günes, 2010).
17. **Check the amount of medication in the syringe with the medication dose and discard any surplus.**	Careful measurement ensures that the correct dose is withdrawn.
18. **Depending on facility policy, the third check of the label may occur at this point. If so, when all medications for one patient have been prepared, read the label and recheck the labels with the eMAR/MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**	This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration.
19. Label the syringe with the medication's name, dose, and amount (The Joint Commission, 2021).	Unlabeled syringes are unidentifiable and may lead to a medication administration error (The Joint Commission, 2021).
20. **If a multidose vial is being used, label the vial with the date and time opened and the beyond-use date (see Special Considerations), and store the vial containing the remaining medication according to facility policy.** Limit the use of multiple-dose vials and dedicate them to a single patient whenever possible (CDC, 2019).	Because the vial is sealed, the medication inside remains sterile and can be used for future injections. Labeling the opened vials with a date, time, and beyond-use date limits its use after a specific time period. Limiting use of multiple-dose vials and dedicating their use to a single patient when possible limits risk of contamination and transfer of microorganisms (CDC, 2019; Dolan et al., 2016).
21. **Log out of and/or lock the medication supply system before leaving it.**	Locking the medication supply system or drawer safeguards the patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use.
	Hand hygiene deters the spread of microorganisms.
22. Perform hand hygiene.	
23. Proceed with administration, based on prescribed route.	See appropriate skill for prescribed route.

DOCUMENTATION

Guidelines

It is not necessary to record the removal of the medication from a vial. Prompt recording of administration of the medication is required immediately after it is administered.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *A piece of self-sealing stopper is noticed floating in the medication in the syringe:* Discard the syringe, needle, and vial. Obtain a new vial, syringe, and needle and prepare the dose as ordered.
- *As the needle attached to the syringe filled with air is inserted into vial, the plunger is immediately pulled down:* If possible to withdraw medication, continue steps as explained above. If such a vacuum has formed that this is impossible, remove the syringe and inject more air into the vial.
- *Plunger is contaminated before injecting air into vial:* Discard the needle and syringe and start over.
- *Plunger is contaminated after medication is drawn into syringe*: It is not necessary to discard the needle and syringe

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and start over. The contaminated plunger will enter the barrel of the syringe when pushing the medication out, will not come in contact with the medication, and will not contaminate the medication.

SPECIAL CONSIDERATIONS

- When mixing medications in one syringe, preparation of medications in one syringe depends on how the medication is supplied. When using a single-dose vial and a multidose vial, inject air into the multidose vial and draw the medication from the multidose vial into the syringe first. This prevents the contents of the multidose vial from being contaminated with the medication in the single-dose vial. The steps to follow when preparing medications from two multidose vials in one syringe are outlined in Skill 30-4.
- Vials used to draw two or more medications into a single syringe must be discarded after use (Dolan et al., 2016).
- Do not administer medication from a single-dose vial to multiple patients (CDC, 2019).
- Limit the use of multiple-dose vials and dedicate them to a single patient whenever possible (CDC, 2019).
- Multiple-dose vials must be labeled with a beyond-use date when first opened, as indicated by facility policy (CDC, 2019).

Skill 30-4 Mixing Medications From Two Vials in One Syringe

DELEGATION CONSIDERATIONS

The preparation of medication from two vials is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the preparation of medication from two vials may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

The preparation of two types of insulin in one syringe is used as the example in the following procedure.

- Two vials of medication (insulin in this example)
- Sterile syringe (insulin syringe in this example)
- Sterile needle (if not already packaged with syringe)
- Antimicrobial swabs
- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in place. Clarify any inconsistencies. Check the patient's health record for allergies.	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy located in a health care facility and to outpatient pharmacies.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and adverse effects of the medications to be administered. Confirm the compatibility of the medications in one syringe. Consider the appropriateness of the medication for this patient.	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication.
 3. Perform hand hygiene.	Hand hygiene prevents the spread of microorganisms.

4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode and scan employee identification, if required.	Locking the supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized users into the system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.
7. Read the eMAR/MAR and read the label when selecting the proper medications from the medication supply system or the patient's medication drawer.	This is the *first* check of the label.
8. Read the label and compare the labels with the eMAR/MAR. Check expiration dates and perform dosage calculations, if necessary. Scan the bar code on the package, if required.	This is the *second* check of the labels. Verify calculations with another nurse to ensure safety, if necessary.
9. If necessary, remove the cap that protects the self-sealing stopper on each vial.	The cap protects the self-sealing top.
10. **If the medication is a suspension (e.g., a modified insulin, such as NPH insulin), roll and agitate the vial to mix it well.**	There is controversy regarding how to mix insulin in suspension. Some sources advise rolling the vial; others advise shaking the vial. Consult facility policy or pharmacist. Regardless of the method used, it is essential that the suspension be mixed well to avoid administering an inconsistent dose.
11. **Scrub the self-sealing stopper top with the antimicrobial swab and allow it to dry.**	The antimicrobial swab removes surface microbial contamination. Allowing the antimicrobial solution to dry completely (5 to 20 seconds) ensures complete antimicrobial effectiveness (Gorski et al., 2021; Slater et al., 2018). Drying also prevents antimicrobial solution from entering the vial on the needle.
12. Remove the cap from the needle by pulling it straight off. Touch the plunger only at the knob. Draw back an amount of air into the syringe that is equal to the dose of modified insulin to be withdrawn.	Pulling the cap off in a straight manner prevents accidental needlestick. Handling the plunger only by the knob ensures sterility of the shaft of the plunger. Before fluid is removed, injection of an equal amount of air is required to prevent the formation of a partial vacuum, because a vial is a sealed container. If not enough air is injected, the negative pressure makes it difficult to withdraw the medication with repeated use.
13. Hold the modified vial on a flat surface. Pierce the self-sealing stopper in the center with the needle tip and inject the measured air into the space above the solution (Figure 1). Do not inject air into the solution. Withdraw the needle.	Unmodified insulin should never be contaminated with modified insulin. Placing air in the modified insulin first without allowing the needle to contact the insulin ensures that the second vial-entered (unmodified) insulin is not contaminated by the medication in the other vial. Air bubbled through the solution could result in withdrawal of an inaccurate amount of medication.
14. Draw back an amount of air into the syringe that is equal to the dose of unmodified insulin to be withdrawn.	A vial is a sealed container. Therefore, injection of an equal amount of air (before fluid is removed) is required to prevent the formation of a partial vacuum. If not enough air is injected, the negative pressure makes it difficult to withdraw the medication.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

15. Hold the unmodified vial on a flat surface. Pierce the self-sealing stopper in the center with the needle tip and inject the measured air into the space above the solution (Figure 2). Do not inject air into the solution. Keep the needle in the vial.	Air bubbled through the solution could result in withdrawal of an inaccurate amount of medication.

FIGURE 1. Injecting air into modified insulin preparation.

FIGURE 2. Injecting air into unmodified insulin vial.

16. Invert the vial of unmodified insulin. Hold the vial in one hand and use the other to withdraw the medication. **Touch the plunger only at the knob. Draw up the prescribed amount of medication while holding the syringe at eye level and vertically** (Figure 3). Turn the vial over and then remove the needle from the vial.	Holding the syringe at eye level facilitates accurate reading, and the vertical position allows easy removal of air bubbles from the syringe. First dose is prepared and is not contaminated by insulin that contains modifiers.
17. Check that there are no air bubbles in the syringe.	The presence of air in the syringe would result in an inaccurate dose of medication.
18. **Check the amount of medication in the syringe with the medication dose and discard any surplus.**	Careful measurement ensures that the correct dose is withdrawn.
19. **Recheck the vial label with the eMAR/MAR.**	This is the *third* check to ensure accuracy and to prevent errors. It must be checked now for the first medication in the syringe, as it is not possible to ensure accuracy once a second drug is in the syringe.
20. Calculate the endpoint on the syringe for the combined insulin amount by adding the number of units for each dose together.	This allows for accurate withdrawal of the second dose.
21. Insert the needle into the modified vial and invert it, **taking care not to push the plunger and inject medication from the syringe into the vial.** Invert the vial of modified insulin. Hold the vial in one hand and use the other to withdraw the medication. **Touch the plunger only at the knob. Draw up the prescribed amount of medication while holding the syringe at eye level and vertically (Figure 4). Take care to withdraw only the prescribed amount.** Turn the vial over and then remove the needle from the vial. Carefully recap the needle. Carefully replace the cap over the needle.	The previous addition of air eliminates the need to create positive pressure. Holding the syringe at eye level facilitates accurate reading. Capping the needle prevents contamination and protects the nurse against accidental needlesticks. A one-handed recap method may be used as long as care is taken to ensure that the needle remains sterile.

FIGURE 3. Withdrawing prescribed amount of unmodified insulin.

FIGURE 4. Withdrawing modified insulin.

22. **Check the amount of medication in the syringe with the medication dose.**
    Careful measurement ensures that correct dose is withdrawn.
23. **Depending on facility policy, the third check of the label may occur at this point. If so, read the label and recheck the labels with the MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**
    This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration.
24. **Label the vials with the date and time opened and beyond-use date, and store the vials containing the remaining medication, according to facility policy.**
    Because the vial is sealed, the medication inside remains sterile and can be used for future injections. Labeling the opened vials with a date and time limits its use after a specific time period. The CDC recommends that medications packaged as multiuse vials be assigned to a single patient whenever possible (CDC, 2019; Dolan et al., 2016).
25. Label the syringe with the medication's name, dose, and amount date (The Joint Commission, 2021).
    Unlabeled syringes are unidentifiable and may lead to a medication administration error (The Joint Commission, 2021).
26. **Log out of and/or lock the medication supply system before leaving it.**
    Locking the medication supply system or drawer safeguards the patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use.

    Hand hygiene deters the spread of microorganisms.
27. Perform hand hygiene.
28. Proceed with administration, based on prescribed route.
    See appropriate skill for prescribed route.

DOCUMENTATION

Guidelines

It is not necessary to record the removal of the medication from the vials. Prompt recording of administration of the medication is required immediately after it is administered.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- *You contaminate the plunger before injecting air into the insulin vial:* Discard the needle and syringe and start over.
- *The plunger is contaminated after medication is drawn into the syringe:* It is not necessary to discard and start over. The contaminated plunger will enter the barrel of the syringe when pushing the medication out and will not contaminate the medication.
- *You allow modified insulin to come in contact with the needle before entering the unmodified insulin vial:* Discard the needle and syringe and start over.
- *You notice that the combined amount is not the ordered amount (i.e., you have less or more units in combined syringe than ordered):* Discard the syringe and start over. There is no way to know for sure which dosage is wrong or which medication should be expelled.
- *You inject medication from the first vial (in syringe) into the second vial:* Discard the vial and syringe and start over.

SPECIAL CONSIDERATIONS

General Considerations

- A patient with diabetes who is visually impaired may find it helpful to use a magnifying apparatus that fits around the syringe.
- Before attempting to explain or demonstrate devices that help low-vision diabetic patients to prepare their medication, attempt to use the device yourself under similar circumstances. To detect any difficulties the patient may experience, practice using the aid with your eyes closed or in a poorly lit room.

Infant and Child Considerations

- School-age children are generally able to prepare and administer their own injections, such as insulin, with supervision (American Academy of Pediatrics, 2020). Parents/caregivers and the child should be involved in teaching.

Skill 30-5 Administering an Intradermal Injection

DELEGATION CONSIDERATIONS

The administration of an intradermal injection is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the administration of an intradermal injection may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Prescribed medication
- Sterile syringe, usually a tuberculin syringe calibrated in tenths and hundredths, and a 3/8″ to ½″, 26- or 27-gauge needle
- Antimicrobial swab
- Disposable gloves
- Small gauze square
- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)
- PPE, as indicated
- Marking pen for indicating area for future assessment, if indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in place. Clarify any inconsistencies. Check the patient's health record for allergies.	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy located in a health care facility and to outpatient pharmacies.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and adverse effects of the medications to be administered. Consider the appropriateness of the medication for this patient.	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication.
 3. Perform hand hygiene.	Hand hygiene deters the spread of microorganisms.
4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode and scan employee identification, if required.	Locking the medication supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized users into the system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

7. Read the eMAR/MAR and read the label when selecting the proper medication from the medication supply system or the patient's medication drawer.	This is the *first* check of the label.
8. Read the label and compare the label with the eMAR/MAR. Check expiration dates and perform calculations, if necessary. Scan the bar code on the package, if required.	This is the *second* check of the label. Verify calculations with another nurse to ensure safety.
9. If necessary, withdraw the medication from an ampule or vial as described in Skills 30-2 and 30-3.	
10. **Depending on facility policy, the third check of the label may occur at this point. If so, when all medications for one patient have been prepared, read the label and recheck the labels with the eMAR/MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**	This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration.
11. Label the syringe with the medication's name, dose, and amount (The Joint Commission, 2021).	Unlabeled syringes are unidentifiable and may lead to a medication administration error (The Joint Commission, 2021).
12. **Log-out of and/or lock the medication supply system before leaving it.**	Locking the medication supply system or drawer safeguards the patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use.
13. Transport medications to the patient's bedside carefully and keep the medications in sight at all times.	Careful handling and close observation prevent accidental or deliberate disarrangement of medications.
14. **Ensure that the patient receives the medications at the correct time.**	Check facility policy, which may allow for administration within a period of 30 minutes before or 30 minutes after the designated time.
 15. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 16. **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two of the following methods** (The Joint Commission, 2021):	Identifying the patient ensures the right patient receives the medications and helps prevent errors. The patient's room number or physical location is not used as an identifier (The Joint Commission, 2021). Replace the identification band if it is missing or inaccurate in any way.
a. Check the name on the patient's identification band.	This requires a response from the patient, but illness and strange surroundings often cause patients to be confused.
b. Check the identification number on the patient's identification band.	
c. Check the birth date on the patient's identification band.	
d. Ask the patient to state their name and birth date, based on facility policy.	
17. Close the door to the room or pull the bedside curtain.	This provides patient privacy.
18. **Complete necessary assessments before administering medications. Check the patient's allergy bracelet, if present, or ask the patient about allergies. Explain the purpose and action of**	Assessment is a prerequisite to administration of medications. Explanation provides rationale, increases knowledge, promotes patient engagement, and reduces anxiety.

the medication to the patient.	
19. Scan the patient's bar code on the identification band, if required (The Joint Commission, 2021).	This provides an additional check to ensure that the medication is given to the right patient.
20. **Based on facility policy, the third check of the label may occur at this point. If so, read the label and recheck the labels with the eMAR/MAR before administering the medications to the patient.**	Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration. If facility policy directs the *third* check at this time, this *third* check ensures accuracy and helps to prevent errors.
21. Put on gloves.	Gloves help prevent exposure to contaminants.
22. Select an appropriate administration site. Assist the patient to the appropriate position for the site chosen. Drape, as needed, to expose only site area to be used.	Using the appropriate site prevents injury and allows for accurate reading of the test site at the appropriate time. Draping provides privacy and warmth.
23. Cleanse the site with an antimicrobial swab while wiping with a firm, circular motion and moving outward from the injection site. Allow the skin to dry.	Pathogens on the skin can be forced into the tissues by the needle. Moving from the center outward prevents contamination of the site. Allowing the antimicrobial solution to dry completely (5 to 20 seconds) ensures complete antimicrobial effectiveness (Gorski et al., 2021; Slater et al., 2018), and prevents introducing alcohol into the tissue, which can be irritating and uncomfortable.
24. Remove the needle cap with the nondominant hand by pulling it straight off.	This technique lessens the risk of an accidental needlestick.
25. Use the nondominant hand to spread the skin taut over the injection site (Figure 1).	Taut skin provides an easy entrance into intradermal tissue.

FIGURE 1. Spreading skin taut over injection site.

26. Hold the syringe in the dominant hand, between the thumb and forefinger with the bevel of the needle up.	Using the dominant hand allows for easy, appropriate handling of the syringe. Having the bevel up allows for smooth piercing of the skin and introduction of medication into the dermis.
27. Hold the syringe at a 5- to 15-degree angle from the site. Place the needle almost flat against the patient's skin (Figure 2), bevel side up, and insert the needle into the skin. Insert the needle only about ⅛ inch with entire bevel under the skin.	The dermis is entered when the needle is held as nearly parallel to the skin as possible and is inserted about ⅛ inch.
28. Once the needle is in place, steady the lower end of the syringe. Slide your dominant hand to the end of the plunger.	This prevents injury and inadvertent advancement or withdrawal of needle.
29. Slowly inject the agent while watching for a small wheal to appear (Figure 3).	The appearance of a wheal indicates the medication is in the dermis.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 2. Inserting needle almost flat against the skin.

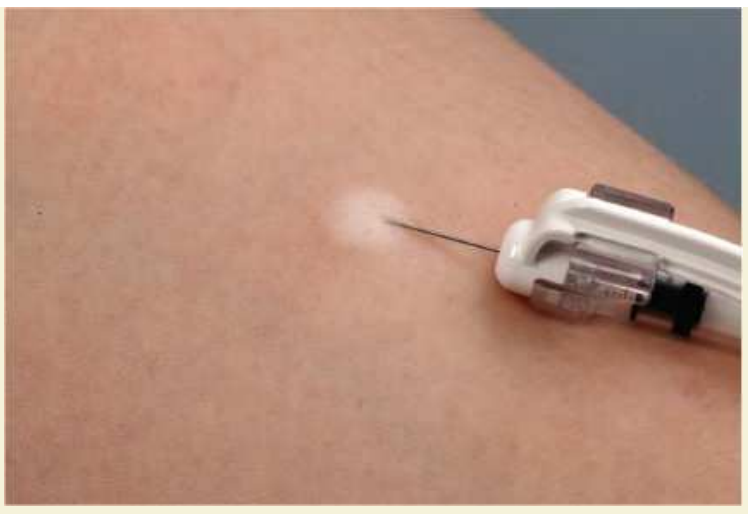


FIGURE 3. Observing for wheal while injecting medication.

30. Withdraw the needle quickly at the same angle that it was inserted. Do not recap the used needle. Engage the safety shield or needle guard.	Withdrawing the needle quickly and at the angle at which it entered the skin minimizes tissue damage and discomfort for the patient. Safety shield or needle guard prevents accidental needlestick injury.
31. **Do not massage the area after removing needle. Tell the patient not to rub or scratch the site. If necessary, gently blot the site with a dry gauze square. Do not apply pressure or rub the site.** Use the marking pen to mark the area for further assessment, if indicated.	Massaging or rubbing the area where an intradermal injection is given may spread the medication to underlying subcutaneous tissue.
32. Remove gloves and perform hand hygiene. Assist the patient to a position of comfort.	Removing gloves and performing hand hygiene reduces risk for contamination of other items and the spread of microorganisms. Assisting the patient to a position of comfort promotes patient comfort.
33. Discard the needle and syringe in an appropriate container, such as a sharps receptacle.	Proper disposal of the needle prevents injury.
34. Remove additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk of infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
35. Document the administration of the medication immediately after administration. See Documentation section below.	Timely documentation helps to ensure patient safety.
36. Evaluate the patient's response to the medication within the appropriate time frame.	The patient needs to be evaluated for therapeutic and adverse effects from the medication.
37. Observe the area for signs of a reaction at determined intervals after administration. Inform the patient of the need for inspection.	With many intradermal injections, you need to look for a localized reaction in the area of the injection at the appropriate interval(s) determined by the type of medication and purpose. Explanation provides rationale, increases knowledge, promotes patient engagement, and reduces anxiety.
38. If medication is intended for allergy skin testing, observe the patient for sensitivity to the injected allergen (Hoy & Ng, 2021).	Sensitivity to an allergen places the patient at risk for the development of anaphylaxis and may require the administration of epinephrine subcutaneously (Hoy & Ng, 2021). (Refer to Skill 30-6.)

DOCUMENTATION

Guidelines

Record each medication administered on the eMAR/MAR or health record using the required format, including date, time, and the site of administration, immediately after administration. Some facilities recommend circling the injection site with ink. Circling the injection site easily identifies the intradermal injection site and allows for future

careful observation of the exact area. If using a bar-code system, medication administration is automatically recorded when the bar code is scanned. PRN medications require documentation of the reason for administration. Prompt recording avoids the possibility of accidentally repeating the administration of the drug. If the drug was refused or omitted, record this in the appropriate area on the medication record and notify the health care team as appropriate. This verifies the reason medication was omitted and ensures that health care personnel providing care for the patient are aware of the occurrence.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *You do not note a wheal or blister at the injection site:* The medication has been inadvertently injected subcutaneously. Document according to facility policy and notify the health care team as appropriate. You may need to obtain an order to repeat the procedure.
- *Medication leaks out of the injection site before the needle is withdrawn:* The needle was inserted less than ⅛ inch. Document according to facility policy and notify the health care team as appropriate. You may need to obtain an order to repeat the procedure.
- *You stick yourself with the needle before injection:* Discard the needle and syringe appropriately. Follow facility policy regarding needlestick injury. Prepare a new syringe with medication and administer to the patient. Communicate and document the incident according to facility policy.
- *You stick yourself with the needle after injection:* Discard the needle and syringe appropriately. Follow facility policy regarding needlestick injury. Communicate and document the incident according to facility policy.

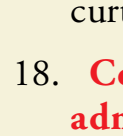
SPECIAL CONSIDERATIONS

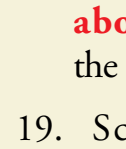
- Fluzone® Intradermal is the only vaccine in the United States administered by the intradermal route and is available for patients ages 18 to 64 years (CDC, 2015; Prescriber's Digital Reference [PDR], 2021; Sanofi Pasteur, 2017). The site of administration for this vaccine is the deltoid region of the upper arm, and the needle is inserted perpendicular to the skin (PDR, 2021). **This vaccine should not be administered into the forearm or other site used to administer other intradermal medications.** The single-dose prefilled microinjection syringe administers a 0.1-mL dose (Sanofi Pasteur, 2017). **No other influenza vaccine formulations should be administered by the intradermal route.** Follow the manufacturer's directions for appropriate administration.
- Ongoing assessment is an important part of nursing care for both evaluation of patient response to administered medications and early detection of adverse reactions. If an adverse effect is suspected, withhold further medication doses and notify the health care team. Additional intervention is based on type of reaction and patient assessment.

Skill 30-6 Administering a Subcutaneous Injection

DELEGATION CONSIDERATIONS

The administration of a subcutaneous injection is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the administration of a subcutaneous injection may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.





EQUIPMENT

- Prescribed medication
- Sterile syringe and needle. Needle size depends on the medication to be administered and patient body type (see previous discussion).
- Antimicrobial swab
- Nonlatex, disposable gloves
- Small gauze square
- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)
- PPE, as indicated

IMPLEMENTATION

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in place. Clarify any inconsistencies. Check the patient's health record for allergies.	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy located in a health care facility and to outpatient pharmacies.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and adverse effects of the medications to be administered. Consider the appropriateness of the medication for this patient.	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication.
 3. Perform hand hygiene.	Hand hygiene prevents the spread of microorganisms.
4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode and scan employee identification, if required.	Locking the medication supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized users into the computer system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.
7. Read the eMAR/MAR and read the label when selecting the proper medication from the medication supply system or the patient's medication drawer.	This is the *first* check of the label.
8. Read the label and compare the medication label with the eMAR/MAR. Check expiration dates and perform calculations, if necessary. Scan the bar code on the package, if required.	This is the *second* check of the label. Verify calculations with another nurse to ensure safety, if necessary.
9. If necessary, withdraw the medication from an ampule or vial as described in Skills 30-2 and 30-3.	
10. **Depending on facility policy, the third check of the label may occur at this point. If so, when all medications for one patient have been prepared, read the label and recheck the labels with the eMAR/MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**	This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration.
11. Label the syringe with the medication's name, dose, and amount (The Joint Commission, 2021).	Unlabeled syringes are unidentifiable and may lead to a medication administration error (The Joint Commission, 2021).
12. **Log out of and/or lock the medication supply system before leaving it.**	Locking the medication supply system or drawer safeguards the patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use.
13. Transport medications to the patient's bedside carefully and keep the medications in sight at all	Careful handling and close observation prevent accidental or deliberate disarrangement of

times.	medications.
14. **Ensure that the patient receives the medications at the correct time.**	Check facility policy, which may allow for administration within a period of 30 minutes before or 30 minutes after the designated time.
 15. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 16. **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two of the following methods** (The Joint Commission, 2021):	Identifying the patient ensures the right patient receives the medications and helps prevent errors. The patient's room number or physical location is not used as an identifier (The Joint Commission, 2021). Replace the identification band if it is missing or inaccurate in any way.
a. Check the name on the patient's identification band.	
b. Check the identification number on the patient's identification band.	
c. Check the birth date on the patient's identification band.	
d. Ask the patient to state their name and birth date, based on facility policy.	This requires a response from the patient, but illness and strange surroundings often cause patients to be confused.
17. Close the door to the room or pull the bedside curtain.	This provides patient privacy.
18. **Complete necessary assessments before administering medications. Check the patient's allergy bracelet, if present, or ask the patient about allergies.** Explain the purpose and action of the medication to the patient.	Assessment is a prerequisite to administration of medications. Explanation provides rationale, increases knowledge, promotes patient engagement, and reduces anxiety.
19. Scan the patient's bar code on the identification band, if required (The Joint Commission, 2021) (Figure 1).	Scanning provides an additional check to ensure that the medication is given to the right patient.
20. **Based on facility policy, the third check of the label may occur at this point. If so, read the label and recheck the labels with the eMAR/MAR before administering the medications to the patient.**	Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration. If facility policy directs the *third* check at this time, this *third* check ensures accuracy and helps to prevent errors.
21. Put on gloves.	Gloves help prevent exposure to contaminants.
22. Select an appropriate administration site. Assist the patient to the appropriate position for the site chosen. Drape, as needed, to expose only site area to be used.	Using an appropriate site and positioning prevent injury. Draping helps maintain the patient's privacy.
23. Identify the appropriate landmarks for the site chosen.	Good visualization is necessary to establish the correct site location and to avoid complications (Taylor et al., 2023).
24. Cleanse the area around the injection site with an antimicrobial swab. Use a firm, circular motion while moving outward from the injection site (Figure 2). Allow the area to dry.	Pathogens on the skin can be forced into the tissues by the needle. Moving from the center outward prevents contamination of the site. Allowing the antimicrobial solution to dry completely (5 to 20 seconds) ensures complete antimicrobial effectiveness (Gorski et al., 2021; Slater et al., 2018), and prevents introducing alcohol into the tissue, which can be irritating and uncomfortable.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 1. Scanning bar code on the patient's identification bracelet. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

FIGURE 2. Cleaning injection site.

25. Remove the needle cap with the nondominant hand, pulling it straight off.

The cap protects the needle from contact with microorganisms. This technique lessens the risk of an accidental needlestick.

26. Hold the syringe in the dominant hand between the thumb and forefinger. Use the thumb, index finger and middle finger on the nondominant hand to pinch up the skin and underlying fatty tissue (Figure 3). Inject the needle quickly at a 45- or 90-degree angle, depending on the amount of underlying subcutaneous tissue (Figure 4).

Pinching up the skin and underlying fatty tissue lifts the adipose tissue away from underlying muscle and tissue (Wolicki & Miller, 2020; Shepard, 2018b). Inserting the needle quickly causes less pain to the patient. For a person with a limited amount of subcutaneous tissue, insert the needle at a 45-degree angle (Shepherd, 2018b).

FIGURE 3. Pinching up the skin and underlying fatty tissue.

FIGURE 4. Inserting needle.

27. Move your nondominant hand to the lower end of the syringe and slide your dominant hand to the end of the plunger, taking care to avoid moving the syringe. Alternatively, move your middle finger into place on the syringe, holding the syringe with your thumb and middle finger, and move your index finger to the end of the plunger; taking care to avoid moving the syringe.

This allows for stabilization of the syringe and avoids movement. Moving the syringe could cause damage to the tissues and inadvertent administration into an incorrect area.

28. Inject the medication. Withdraw the needle quickly at the same angle at which it was inserted, while supporting the surrounding tissue with your nondominant hand.

Slow withdrawal of the needle pulls the tissues and causes discomfort. Applying counter traction around the injection site helps to prevent pulling on the tissue as the needle is withdrawn. Removing the needle at the same angle at which it was inserted minimizes tissue damage and discomfort for the patient.

29. Do not recap the used needle. Engage the safety shield or needle guard.

Safety shield or needle guard prevents accidental needlestick.

30. If blood or clear fluid appears at the site after withdrawing the needle, use a gauze square to apply gentle pressure to the site. **Do not massage the site.**

Massaging the site can damage underlying tissue and increase the absorption of the medication (Taylor et al., 2023). Massaging after heparin administration

	can contribute to hematoma formation.
 31. Remove gloves and perform hand hygiene. Assist the patient to a position of comfort.	Removing gloves and performing hand hygiene reduces the risk of contamination of other items and the spread of microorganisms. Assisting the patient to a position of comfort promotes patient comfort.
32. Discard the needle and syringe in an appropriate container, such as a sharps receptacle.	Proper disposal of the needle prevents injury.
 33. Remove additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk of infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
34. Document the administration of the medication immediately after administration.	Timely documentation helps to ensure patient safety.
35. Evaluate the patient's response to the medication within the appropriate time frame for the particular medication.	The patient needs to be evaluated for therapeutic and adverse effects from the medication.

DOCUMENTATION

Guidelines

Record each medication given on the eMAR/MAR or health record using the required format immediately after administration, including date, dose, time, and the site of administration. If using a bar-code system, medication administration is automatically recorded when the bar code is scanned. PRN medications require documentation of the reason for administration. Prompt recording avoids the possibility of accidentally repeating the administration of the drug. If the drug was refused or omitted, record this in the appropriate area on the medication record and notify the health care team as appropriate. This verifies the reason medication was omitted and ensures that health care personnel providing care for the patient are aware of the occurrence.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient refuses to let you administer medication in a different location:* Explain the rationale behind rotating injection sites. Discuss other available injection sites with the patient. If the patient will still not allow injection in another area, administer medication to patient, document the patient's refusal of rotation of the injection site and discussion, and notify the health care team.
- *You stick yourself with the needle before injection:* Discard the needle and syringe appropriately. Follow facility policy regarding needlestick injury. Prepare a new syringe with medication and administer to the patient. Communicate and document the incident according to facility policy.
- *You stick yourself with the needle after injection:* Discard the needle and syringe appropriately. Communicate and document the incident according to facility policy.
- *During injection, patient pulls away from the needle before the medication is delivered fully:* Remove and appropriately discard the needle. Attach a new needle to the syringe and administer the remaining medication at a different site. Document events and interventions according to facility policy.

SPECIAL CONSIDERATIONS

General Considerations

- Ongoing assessment is an important part of nursing care for both evaluation of patient response to administered medications and early detection of adverse drug reactions. If an adverse effect is suspected, withhold further medication doses and notify the health care team. Additional intervention is based on type of reaction and patient assessment.
- Injection speed does not seem to influence pain sensation associated with subcutaneous injection (Heise et al., 2014; Mohammady et al., 2017; Pich, 2020; Zijlstra et al., 2018).
- Because absorption rates vary from site to site, it is recommended that patients administering their own insulin use the same area of the body at the same time every day to ensure more consistent absorption and prevent tissue changes from repeated use of the same site (ADA, 2020; Frandsen & Pennington, 2021; Karch, 2020). For instance,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

every morning the patient may use the abdomen for insulin injection, and every evening before dinner, the patient may inject the insulin into the arms or thighs. Keep in mind that the best absorption occurs in the abdomen. In each case, the injections should be given an inch away from the previous injection site. A small spot bandage or piece of tape can be used to mark the first injection site, with subsequent injections rotated in a circle around that site. After this area has been used, an adjacent site, an inch away, can be selected, using the same rotation format. A marked diagram incorporated into the patient's plan of care is also helpful for noting alternative sites. Patients should be encouraged to not rely on memory. The patient cannot always recall the site of the previous injection, therefore, the site of administration should be recorded. When the patient is receiving care from a health care provider, the site of administration must be recorded in the patient's health record.

- Heparin is administered subcutaneously. The abdomen is the most commonly used administration site. Avoid the area 2 inches around the umbilicus and the belt line.
- Certain medications have specific manufacturer-recommended administration requirements. For example, enoxaparin (low–molecular-weight heparin) should be administered alternating between the left and right anterolateral and left and right posterolateral abdominal wall (Sanofi-Aventis, 2020) (Figure 5). To administer the medication, pinch the tissue gently to form a skin fold and insert the needle at a 90-degree angle (Sanofi-Aventis, 2020). Enoxaparin is packaged in a prefilled syringe with an air bubble. **Do not expel the air bubble before administration** (Sanofi-Aventis, 2020).

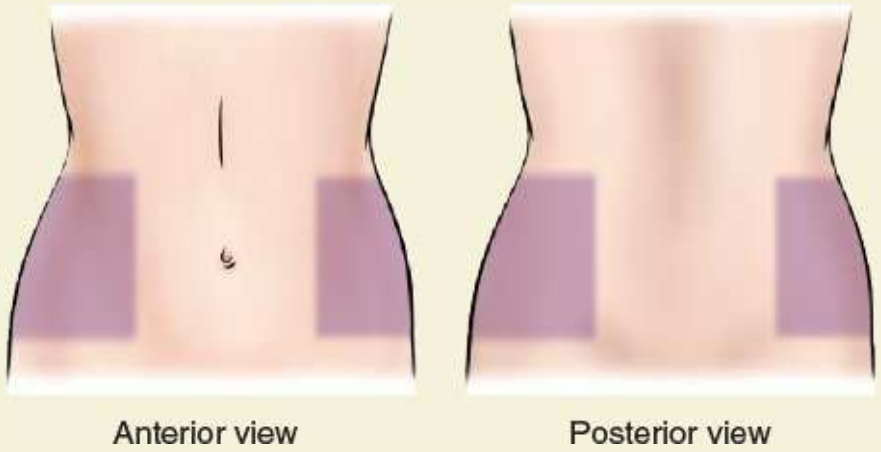


FIGURE 5. Sites for administration of enoxaparin.

Infant and Child Considerations

- Do not tell a child that an injection will not hurt. Describe the feel of the injection as a pinch or a sting. A child who believes you have been dishonest is less likely to cooperate with future procedures.

Older Adult Considerations

- Many older adults have less adipose tissue. Adjust the needle length and insertion angle accordingly. (Refer to discussion earlier in Skill.) You do not want to inadvertently give a subcutaneous medication intramuscularly.

Community-Based Care Considerations

- Reuse of syringes in the home setting is not recommended.
- The use of antimicrobial swabs to clean the injection site in home environments may be unnecessary; patients may use soap and water to clean the site if the area is visibly soiled (Sexson et al., 2016).
- Because absorption rates vary from site to site, it is recommended that patients administering their own insulin use the same area of the body at the same time every day to ensure more consistent absorption and prevent tissue changes from repeated use of the same site (ADA, 2020; Frandsen & Pennington, 2021). Refer to the information discussed in the "General Considerations" section of this Skill.
- Encourage patients to consult the policies of their local government regarding contaminated and sharps waste disposal.
- The U.S. Food & Drug Administration (FDA, 2021) recommends a two-step process for properly disposing of used needles and other sharps by patients, family members, and caregivers: (1) Needles and other sharps should be placed in a sharps disposal container immediately after they have been used to reduce the risk of needle sticks, cuts, and punctures from loose sharps. (2) Used sharps disposal containers should be disposed of according to community guidelines; guidelines and disposal programs vary depending on location. Patients should consult local trash removal services and the local health department to identify available disposal methods. Never use glass containers.
- Sharps disposal methods (depending on community location) include drop boxes or supervised collection sites, household hazardous waste collection sites, mail-back programs, and residential special waste pick-up services (FDA, 2021).
- If a patient, family member, or caregiver does not want to purchase a sharps container, an empty laundry detergent or bleach bottle may be used. It must be a strong plastic container with a screw-on lid, *not* an empty plastic water or soda bottle or other type of thin plastic container (SafeNeedleDisposal.org, 2021). Label the container as sharps and

not for recycling. The screw-on top should be used to close the container for disposal, and containers should be sealed with strong tape (e.g., duct tape) (SafeNeedleDisposal.org, 2021).

- Sharps disposal containers should be kept out of reach of children and pets (FDA, 2021).
- The Safe Needle Disposal resource page provides information on needle disposal takeback programs and an interactive tool to locate state waste links (FDA, 2021; SafeNeedleDisposal.org, 2021).

Skill 30-7 Administering an Intramuscular Injection

DELEGATION CONSIDERATIONS

The administration of an intramuscular injection is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the administration of an intramuscular injection may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Gloves
- Additional PPE, as indicated
- Prescribed medication
- Sterile syringe and needle of appropriate size and gauge
- Antimicrobial swab
- Small gauze square
- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in place. Clarify any inconsistencies. Check the patient's health record for allergies.	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy located in a health care facility and to outpatient pharmacies.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and adverse effects of the medications to be administered. Consider the appropriateness of the medication for this patient.	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication.
	Hand hygiene prevents the spread of microorganisms.
3. Perform hand hygiene.	
4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode and scan employee identification, if required.	Locking the medication supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	users into the system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.
7. Read the eMAR/MAR and read the label when selecting the proper medication from the medication supply system or the patient's medication drawer.	This is the *first* check of the label.
8. Read the label and compare the label with the eMAR/MAR. Check expiration dates and perform calculations, if necessary. Scan the bar code on the package, if required.	This is the *second* check of the label. Verify calculations with another nurse to ensure safety, if necessary.
9. If necessary, withdraw the medication from an ampule or vial as described in Skills 30-2 and 30-3.	
10. **Depending on facility policy, the third check of the label may occur at this point. If so, when all medications for one patient have been prepared, read the label and recheck the labels with the eMAR/MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**	This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration.
11. Label the syringe with the medication's name, dose, and amount (The Joint Commission, 2021).	Unlabeled syringes are unidentifiable and may lead to a medication administration error (The Joint Commission, 2021).
12. **Log out of and/or lock the medication supply system before leaving it.**	Locking the medication supply system or drawer safeguards the patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use.
13. Transport medications to the patient's bedside carefully and keep the medications in sight at all times.	Careful handling and close observation prevent accidental or deliberate disarrangement of medications.
14. **Ensure that the patient receives the medications at the correct time.**	Check facility policy, which may allow for administration within a period of 30 minutes before or 30 minutes after the designated time.
 15. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 16. **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two of the following methods** (The Joint Commission, 2021):	Identifying the patient ensures the right patient receives the medications and helps prevent errors. The patient's room number or physical location is not used as an identifier (The Joint Commission, 2021). Replace the identification band if it is missing or inaccurate in any way.
a. Check the name on the patient's identification band.	This requires a response from the patient, but illness and strange surroundings often cause patients to be confused.
b. Check the identification number on the patient's identification band.	
c. Check the birth date on the patient's identification band.	
d. Ask the patient to state their name and birth date, based on facility policy.	
17. Close the door to the room or pull the bedside curtain.	This provides patient privacy.

18. **Complete necessary assessments before administering medications. Check the patient's allergy bracelet, if present, or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**	Assessment is a prerequisite to administration of medications. Explanation provides rationale, increases knowledge, promotes patient engagement, and reduces anxiety.
19. Scan the bar code on the patient's identification band, if required (Figure 1) (The Joint Commission, 2021).	This provides an additional check to ensure that the medication is given to the right patient.
20. **Based on facility policy, the third check of the label may occur at this point. If so, read the label and recheck the labels with the eMAR/MAR before administering the medications to the patient.**	Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration. If facility policy directs the *third* check at this time, this *third* check ensures accuracy and helps to prevent errors.
21. Put on gloves.	Gloves help prevent exposure to contaminants.
22. Select an appropriate administration site. Assist the patient to the appropriate position for the site chosen. Drape, as needed, to expose only the site area being used.	Selecting the appropriate site and appropriate positioning prevent injury. Draping provides privacy and warmth.
23. **Identify the appropriate landmarks and site boundaries for the site chosen (Figure 2).**	Good visualization is necessary to establish the correct site location and to avoid complications (Taylor et al., 2023).

FIGURE 1. Scanning bar code on the patient's identification bracelet.

FIGURE 2. Identifying the appropriate landmarks.

24. Cleanse the site with an antimicrobial swab while wiping with a firm, circular motion and moving outward from the injection site. Consider leaving the alcohol pad on the skin with the tip of the pad pointing toward the center of the area you just prepared. Allow the skin to dry.	Pathogens on the skin can be forced into the tissues by the needle. Moving from the center outward prevents contamination of the site. Allowing the antimicrobial solution to dry completely (5 to 20 seconds) ensures complete antimicrobial effectiveness (Gorski et al., 2021; Slater et al., 2018), and prevents introducing alcohol into the tissue, which can be irritating and uncomfortable.
25. Remove the needle cap by pulling it straight off. Hold the syringe in your dominant hand between the thumb and forefinger.	This technique lessens the risk of an accidental needlestick and also prevents inadvertently unscrewing the needle from the barrel of the syringe.
26. Displace the skin in a Z-track manner. Pull or shift the skin and underlying tissue down or to one side 1 to 2 cm (Karch, 2020; Yilmaz et al., 2016) with your nondominant hand and hold the skin and tissue in this position (Figure 3). Alternatively, based on assessment of the particular circumstances for an individual patient, if the nurse decides not to use the Z-track technique, the skin should be stretched flat between two fingers and held taut for needle insertion.	Z-track technique is recommended for all intramuscular injections to ensure medication does not leak back along the needle track and into the subcutaneous tissue (Hopkins & Arias, 2013; Yilmaz et al., 2016). This technique reduces pain and discomfort, particularly for patients receiving injections over an extended period. The Z-track method is also suggested for older adults who have decreased muscle mass. Some agents, such as iron, are best given via the Z-track method due to the irritation and discoloration associated with this agent.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

27. Quickly dart the needle into the tissue so that the needle is perpendicular to the patient's body, administering at an angle of 90 degrees (CDC, 2021) (Figure 4).

A quick injection is less painful. Inserting the needle at a 90-degree angle facilitates entry into muscle tissue.

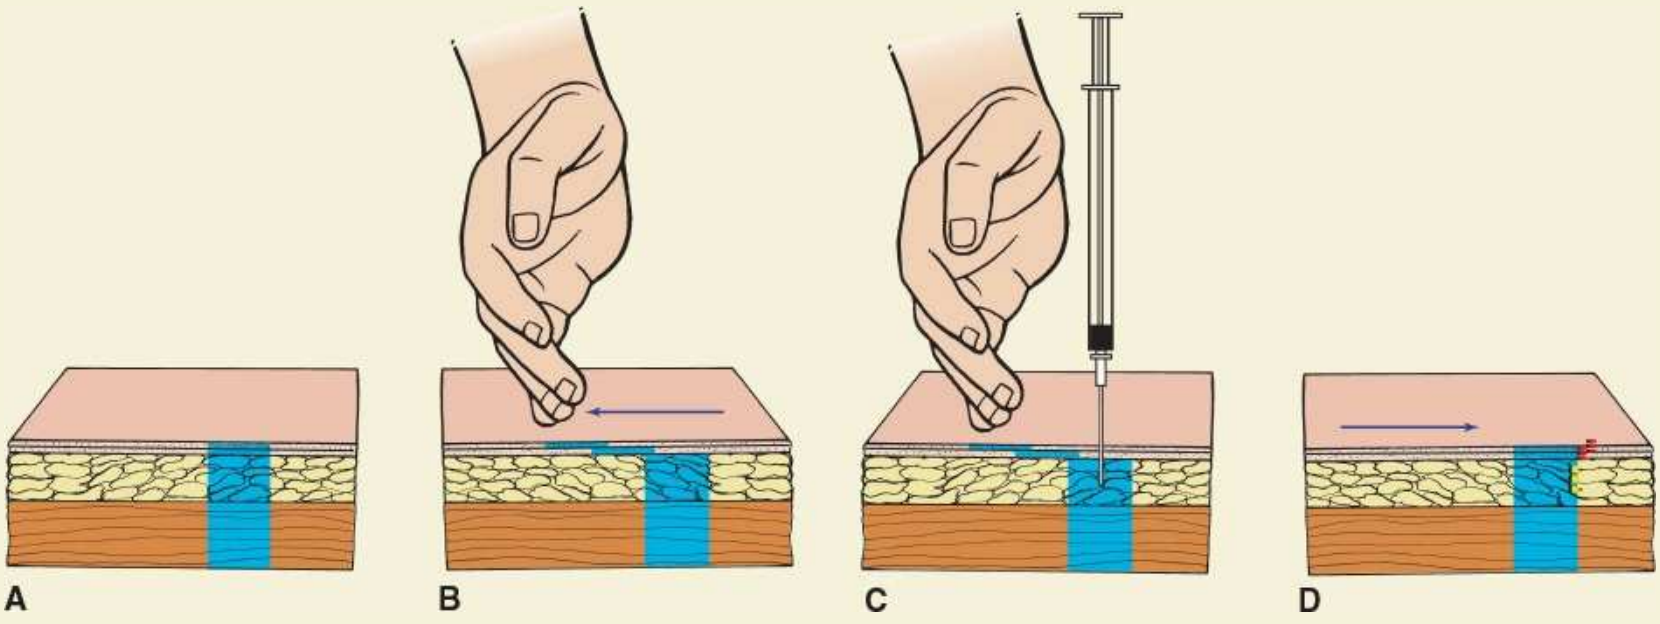

FIGURE 3. Z-track or zigzag technique is recommended for intramuscular injections. **A.** Normal skin and tissues. **B.** Pulling or shifting the skin and underlying tissue down or to one side. **C.** Needle is inserted at a 90-degree angle. **D.** Once needle is withdrawn, displaced tissue is allowed to return to its normal position, preventing solution from escaping from muscle tissue. Hand and finger positioning is adjusted for the specific administration site for accurate identification of landmarks and use of safe injection technique.

FIGURE 4. Darting needle into tissue.

28. As soon as the needle is in place, use the thumb and forefinger of your nondominant hand to hold the lower end of the syringe, taking care to maintain the displacement of the skin and tissue. Slide your dominant hand to the end of the plunger. Inject the solution slowly.

Moving the syringe could cause damage to the tissues and inadvertent administration into an incorrect area. Rapid injection of the solution creates pressure in the tissues, resulting in discomfort.

29. Once the medication has been instilled, wait 10 seconds before withdrawing the needle.

This allows medication to begin to diffuse into the surrounding muscle tissue (Gutierrez & Munakomi, 2021).

30. Withdraw the needle smoothly and steadily at the same angle at which it was inserted, supporting tissue around the injection site with your nondominant hand. **Remove the hand holding the displaced skin and tissue only after removal of the needle, allowing the displaced skin and tissue to return to its normal position.**

Slow withdrawal of the needle pulls the tissues and causes discomfort. Applying counter traction around the injection site helps to prevent pulling on the tissue as the needle is withdrawn. Removing the needle at the same angle at which it was inserted minimizes tissue damage and discomfort for the patient. Allowing displaced skin and tissue to move back into place while needle is still inserted causes damage to the tissues.

31. Do not recap the used needle. Engage the safety shield or needle guard.

A safety shield or needle guard prevents accidental needlestick.

32. Apply gentle pressure at the site with a dry gauze (Figure 5). **Do not massage the site.**

Light pressure causes less trauma and irritation to the tissues. Massaging can force medication into

subcutaneous tissues and increase discomfort.

FIGURE 5. Applying gentle pressure at injection site.

33. Remove gloves and perform hand hygiene. Assist the patient to a position of comfort.	Removing gloves and performing hand hygiene reduces the risk of contamination of other items and the spread of microorganisms. Assisting the patient to a position of comfort promotes patient comfort.
34. Discard the needle and syringe in the appropriate container, such as a sharps receptacle.	Proper disposal of the needle prevents injury.
35. Remove gloves and additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk of infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
36. Document the administration of the medication immediately after administration. See Documentation section below.	Timely documentation helps to ensure patient safety.
37. Evaluate the patient's response to the medication within the appropriate time frame. Assess site, if possible, within 2 to 4 hours after administration.	The patient needs to be evaluated for therapeutic and adverse effects from the medication. Visualization of the site allows for assessment of any untoward effects.

Documentation

Guidelines

Record each medication given on the eMAR/MAR or record using the required format, including date, time, and the site of administration, immediately after administration. If using a bar-code system, medication administration is automatically recorded when the bar code is scanned. PRN medications require documentation of the reason for administration. Prompt recording avoids the possibility of accidentally repeating the administration of the drug. If the drug was refused or omitted, record this in the appropriate area on the medication record and notify the health care team as appropriate. This verifies the reason medication was omitted and ensures that health care personnel providing care for the patient are aware of the occurrence.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *You stick yourself with the needle before injection:* Discard the needle and syringe appropriately. Follow facility policy regarding needlestick injury. Prepare a new syringe with the medication and administer to the patient. Communicate and document the incident according to facility policy.
- *You stick yourself with the needle after injection:* Discard the needle and syringe appropriately. Follow facility policy regarding needlestick injury. Communicate and document the incident according to facility policy.
- *During injection, the patient pulls away from the needle before the medication is delivered fully:* Remove and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

appropriately discard the needle. Attach a new needle to the syringe and administer the remaining medication at a different site. Document events and interventions, according to facility policy.

- *While injecting the needle into the patient, you hit patient's bone:* Withdraw and discard the needle. Apply a new needle to the syringe and administer in an alternate site. Document the incident in the patient's health record. Notify the health care team. Communicate and document the incident according to facility policy.

SPECIAL CONSIDERATIONS

General Considerations

- Ongoing assessment is an important part of nursing care for both evaluation of patient response to administered medications and early detection of adverse drug reactions. If an adverse effect is suspected, withhold further medication doses and notify the health care team. Additional intervention is based on the type of reaction and patient assessment.
- The deltoid is the recommended site for vaccines for adults and may be used for children ages 3 to 18 years for vaccine administration (CDC, 2021).

Infant and Child Considerations

- The vastus lateralis is the preferred site for intramuscular injections in infants (age 12 months and younger) and young children (ages 1 to 2 years) (CDC, 2021). The deltoid can be used in children ages 1 to 2 years if the deltoid muscle mass is adequate (CDC, 2021).
- The deltoid is the preferred site for children ages 3 to 18 years (CDC, 2021).

Older Adult Considerations

- Muscle mass atrophies as a person ages. Take care to evaluate the patient's muscle mass and body composition. Use an appropriate needle length and gauge for patient's body composition. Choose an appropriate site based on the patient's body composition.

Community-Based Care Considerations

- The use of antimicrobial swabs to clean the injection site in home environments may be unnecessary; patients may use soap and water to clean the site if the area is visibly soiled (Sexson et al., 2016).
- Encourage patients to consult the policies of their local government regarding contaminated and sharps waste disposal.
- The U.S. Food & Drug Administration (FDA, 2021) recommends a two-step process for properly disposing of used needles and other sharps by patients, family members, and caregivers. (1) Needles and other sharps should be placed in a sharps disposal container immediately after they have been used to reduce the risk of needle sticks, cuts, and punctures from loose sharps. (2) Used sharps disposal containers should be disposed of according to community guidelines; guidelines and disposal programs vary depending on location. Patients should consult local trash removal services and the local health department to identify available disposal methods. Never use glass containers.
- Sharps disposal methods (depending on community location) include drop boxes or supervised collection sites, household hazardous waste collection sites; mail-back programs, and residential special waste pick-up services (FDA, 2021).
- If a patient, family member, or caregiver does not want to purchase a sharps container, an empty laundry detergent or bleach bottle may be used; it must be a strong plastic container with a screw-on lid, *not* an empty plastic water or soda bottle or other type of thin plastic container (SafeNeedleDisposal.org, 2021). Label the container as sharps and not for recycling. The screw-on top should be used to close the container for disposal, and containers should be sealed with strong tape (e.g., duct tape) (SafeNeedleDisposal.org, 2021).
- Sharps disposal containers should be kept out of reach of children and pets (FDA, 2021).
- The Safe Needle Disposal resource page provides information on needle disposal takeback programs and an interactive tool to locate state waste links (FDA, 2021; SafeNeedleDisposal.org, 2021).

Skill 30-8 Administering Medications by Intravenous Bolus or Push Through an Intravenous Infusion

DELEGATION CONSIDERATIONS

The administration of medications by intravenous bolus is not delegated to assistive personnel (AP). Depending on the

state's nurse practice act and the organization's policies and procedures, the administration of specified intravenous medications in some settings may be delegated to licensed practical/vocational nurses (LPN/LVNs) who have received appropriate training. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Antimicrobial swab
- Watch or clock with second hand
- Gloves
- Additional PPE, as indicated
- Prescribed medication
- Two normal saline flushes prepared in a syringe (3 to 10 mL) according to facility policy
- Passive disinfection caps (based on facility policy)
- Syringe with a needleless device or 23- to 25-gauge, 1-inch needle (follow facility policy)
- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in place. Clarify any inconsistencies. Check the patient's health record for allergies. Check a drug resource to clarify whether the medication needs to be diluted before administration. Check the administration rate.	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy located in a health care facility and to outpatient pharmacies. Compatibility of medication and solution prevents complications. Delivers the correct dose of medication as prescribed.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and adverse effects of the medications to be administered. Consider the appropriateness of the medication for this patient.	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication.
 3. Perform hand hygiene.	Hand hygiene prevents the spread of microorganisms.
4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode and scan employee identification, if required.	Locking the medication supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized users into the system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.
7. Read the eMAR/MAR and select the proper medication from the medication supply system or the patient's medication drawer.	This is the *first* check of the label.
8. Compare the label with the eMAR/MAR. Check expiration dates and perform calculations, if	This is the *second* check of the label. Verify calculations with another nurse to ensure safety, if necessary.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

necessary. Scan the bar code on the package, if required.	
9. If necessary, withdraw the medication from an ampule or vial as described in Skills 30-2 and 30-3.	
10. **Depending on facility policy, the third check of the label may occur at this point. If so, when all medications for one patient have been prepared, recheck the labels with the eMAR/MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**	This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration.
11. Label the syringe with the medication's name, dose, and amount (The Joint Commission, 2021).	Unlabeled syringes are unidentifiable and may lead to a medication administration error (The Joint Commission, 2021). Appropriately label all clinician-prepared syringes of IV push medications or solutions, unless the medication or solution is prepared at the patient's bedside and is immediately administered to the patient (ISMP, 2015, p. 12).
12. **Log out of and/or lock the medication supply system before leaving it.**	Locking the medication supply system or drawer safeguards the patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use.
13. Transport medications and equipment to the patient's bedside carefully and keep the medications in sight at all times.	Careful handling and close observation prevent accidental or deliberate disarrangement of medications. Having equipment available saves time and facilitates performance of the task.
14. **Ensure that the patient receives the medications at the correct time.**	Check facility policy, which may allow for administration within a period of 30 minutes before or 30 minutes after the designated time.
 15. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 16. **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two of the following methods** (The Joint Commission, 2021):	Identifying the patient ensures the right patient receives the medications and helps prevent errors. The patient's room number or physical location is not used as an identifier (The Joint Commission, 2021). Replace the identification band if it is missing or inaccurate in any way.
a. Check the name on the patient's identification band.	This requires a response from the patient, but illness and strange surroundings often cause patients to be confused.
b. Check the identification number on the patient's identification band.	
c. Check the birth date on the patient's identification band.	
d. Ask the patient to state their name and birth date, based on facility policy.	
17. Close the door to the room or pull the bedside curtain.	This provides patient privacy.
18. **Complete necessary assessments before administering medications. Check the patient's allergy bracelet, if present, or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**	Assessment is a prerequisite to administration of medications. Explanation provides rationale, increases knowledge, and reduces anxiety.

19. Scan the patient's bar code on the identification band, if required (The Joint Commission, 2021).	This provides an additional check to ensure that the medication is given to the right patient.
20. **Based on facility policy, the third check of the label may occur at this point. If so, recheck the label with the eMAR/MAR before administering the medications to the patient.**	Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration. If facility policy directs the *third* check at this time, this *third* check ensures accuracy and helps to prevent errors.
21. Assess the IV site for the presence of inflammation or infiltration or other signs of complications.	IV medication must be given directly into a vein for safe administration.
22. If the IV infusion is being administered via an infusion pump, pause the pump.	Pausing prevents infusion of fluid during bolus administration and activation of pump occlusion alarms.
23. Put on gloves.	Gloves prevent contact with blood and body fluids.
24. Select the injection port on the administration set that is closest to the patient. Close the clamp on the administration set immediately above the injection port (Figure 1). Do not disconnect the administration set from the venous access device hub (Gorski et al., 2021).	Using the port closest to the needle insertion site minimizes dilution of the medication. Closing the clamp immediately above the access port ensures the medication is administered to the patient and prevents the medication from backing up the tubing.

FIGURE 1. Closing the clamp on the administration set.

25. Remove the passive disinfection cap from the needleless connector or end cap on the infusion set injection port (Figure 2). Alternatively, if a passive disinfection cap is not in place, use an antimicrobial swab to vigorously disinfect the connection surface and sides of the needleless connector or end cap on the injection port and allow it to dry.	The passive disinfection caps contain an antiseptic-impregnated sponge that dispenses the antiseptic over the connector's top and threads, and provides continuous disinfection of the needleless connection versus intermittent disinfection when using antimicrobial wipes (Barton, 2019; Casey et al., 2018). Venous access device entry points, end caps, and needleless connectors must be vigorously scrubbed and disinfected prior to each access to reduce the risk for introduction of microorganisms and prevent venous access device–related infection (Flynn et al., 2019; Gorski et al., 2021). Friction is needed to physically remove microorganisms from the top, sides, and threads of the needleless connector or end cap. Allow the antiseptic to dry completely to ensure complete effectiveness (Gorski et al., 2021; Slater et al., 2018).
26. Uncap the saline flush syringe. Insert the saline flush syringe into the needleless connector or end cap on the injection port on the administration tubing (Figure 3).	Assessing patency of the venous access device is necessary to ensure IV administration of the medication.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 2. Removing the passive disinfection cap.

FIGURE 3. Inserting the saline flush syringe into the injection port.

27. Pull back on the syringe plunger to aspirate the catheter for positive blood return (Figure 4). If positive, instill the solution over 1 minute or according to facility policy. Remove the syringe.

Positive blood return confirms patency before administration of medications and solutions (Gorski et al., 2021). Flushing without incident ensures patency of the IV line and administration of the medication into the bloodstream.

FIGURE 4. Pulling back on the plunger to aspirate for a blood return.

28. Use an antimicrobial swab to vigorously disinfect the connection surface and sides of the needleless connector or end cap on the injection port and allow it to dry.

Venous access device entry points, end caps, and needleless connectors must be vigorously scrubbed and disinfected prior to each access to reduce the risk for introduction of microorganisms and prevent venous access device–related infection (Flynn et al., 2019; Gorski et al., 2021). Friction is needed to physically remove microorganisms from the top, sides, and threads of the needleless connector or end cap. Allow the antiseptic to dry completely to ensure complete effectiveness (Gorski et al., 2021; Slater et al., 2018).

29. Uncap the medication syringe. Insert the medication syringe into the needleless connector or end cap on the injection port. Using a watch or clock with a second-hand to time the rate, **inject the medication at the recommended rate (Figure 5).**

This delivers the correct amount of medication at the proper interval.

FIGURE 5. Injecting medication at the recommended rate.

30. While administering the medication, observe the infusion site and assess the patient for any adverse reaction. If signs of adverse reaction occur, stop the infusion immediately and notify the health care team.	Signs of adverse reaction, such as peripheral IV infiltration, rash or itching, or pain at the infusion site, necessitate stopping administration of the drug (Gorski et al, 2021).
31. Detach the medication syringe. Use a new antimicrobial swab to vigorously disinfect the connection surface and sides of the needleless connector or end cap on the injection port and allow it to dry. Uncap the second saline flush syringe. Insert the saline flush syringe into the needleless connector or end cap on the injection port. Instill the flush solution at the same rate as the administered medication (Gorski et al., 2021).	Venous access device entry points, end caps, and needleless connectors must be vigorously scrubbed and disinfected prior to each access to reduce the risk for introduction of microorganisms and prevent venous access device–related infection (Flynn et al., 2019; Gorski et al., 2021). Friction is needed to physically remove microorganisms from the top, sides, and threads of the needleless connector or end cap. Allow the antiseptic to dry completely to ensure complete effectiveness (Gorski et al., 2021; Slater et al., 2018). Flushing after medication administration ensures the entire drug dose has been cleared from the extension tubing on the venous access device or from the infusion system and prevents precipitation due to solution/medication incompatibility (Gorski et al., 2021).
32. Remove the flush syringe. Unclamp the administration set above the injection port.	Clamping prevents air from entering the extension set on a capped venous access device. Unclamping the administration set allows for resumption of the continuous IV infusion.
33. Using an antimicrobial swab, vigorously disinfect the connection surface and sides of the needleless connector or end cap on the injection port and allow it to dry. Attach a passive disinfection cap to the needleless connector or end cap on the extension tubing or the injection port on the administration set (Figure 6).	Venous access device entry points, end caps, and needleless connectors must be vigorously scrubbed and disinfected prior to each access to reduce the risk for introduction of microorganisms and prevent venous access device–related infection (Flynn et al., 2019; Gorski et al., 2021). Friction is needed to physically remove microorganisms from the top, sides, and threads of the needleless connector or end cap. Allow the antiseptic to dry completely to ensure complete effectiveness (Gorski et al., 2021; Slater et al., 2018). Passive disinfection caps contain an antiseptic-impregnated sponge that dispenses the antiseptic over the connector's top and threads and protect the hub from contamination by touch or airborne sources (Barton, 2019; Casey et al., 2018).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 6. Attaching a passive disinfection cap.

34. Remove gloves and perform hand hygiene. Restart the infusion pump and check IV fluid infusion rate.	Removing gloves and performing hand hygiene prevents the spread of microorganisms. Restarting the infusion pump resumes the prescribed continuous infusion of fluid. Checking the IV fluid infusion rate assures accuracy in administration.
35. Discard the syringe in the appropriate receptacle.	Proper disposal prevents injury and spread of microorganisms.
36. Remove additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk of infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
37. Document the administration of the medication immediately after administration. See Documentation section below.	Timely documentation helps to ensure patient safety.
38. Evaluate the patient's response to the medication within the appropriate time frame.	The patient needs to be evaluated for therapeutic and adverse effects from the medication.

DOCUMENTATION

Guidelines

Document the administration of the medication immediately after administration, including date, time, dose, route of administration, site of administration, and rate of administration on the eMAR/MAR or record using the required format. If using a bar-code system, medication administration is automatically recorded when the bar code is scanned. PRN medications require documentation of the reason for administration. Prompt recording avoids the possibility of accidentally repeating the administration of the drug. If the drug was refused or omitted, record this in the appropriate area on the medication record and notify the health care team as appropriate. This verifies the reason medication was omitted and ensures that health care personnel providing care for the patient are aware of the occurrence.

Developing Clinical Reasoning and Clinical Judgment

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Upon assessing the IV site before administering medication, no blood return is visible upon aspiration:* If the IV appears patent, without signs of infiltration, and IV fluid infuses without difficulty, proceed with administration. Observe closely for signs and symptoms of infiltration during and after administration.
- *Upon assessing the patient's IV site before administering medication, you note that IV has infiltrated:* Stop the IV fluid and remove the IV from the patient's extremity. Restart the IV in a different location. Continue to monitor the new IV site as medication is administered.
- *While administering medication, you note a cloudy, white substance forming in the IV tubing:* Stop administering the medication. Clamp the IV at the site nearest to the patient. Change the administration tubing and restart the infusion. Check a drug resource or consult a pharmacist regarding compatibility of the medication and IV fluid before continuing with administration. Medication infusion may require a second IV site.

- *While you are administering the medication, the patient begins to complain of pain at the IV site:* Stop the medication. Assess the IV site for any signs of infiltration or phlebitis. Flush the IV with normal saline to check for patency. If the IV site appears within normal limits, resume medication administration at a slower rate.

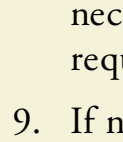
SPECIAL CONSIDERATIONS

- Do not withdraw IV push medications from commercially available, cartridge-type syringes into another syringe for administration. Using the cartridge as a vial can lead to contamination and/or dosing errors, drug mix-ups, and other medication errors (ISMP, 2015, p. 11).
- Do not dilute or reconstitute IV push medications by drawing up the contents into a commercially available, prefilled flush syringe of 0.9% sodium chloride. These devices have been approved for flushing of vascular access devices, but have not been approved for the reconstitution, dilution, and/or subsequent administration of IV push medications (ISMP, 2015, p. 11).
- Appropriately label all clinician-prepared syringes of IV push medications or solutions, unless the medication or solution is prepared at the patient's bedside and is immediately administered to the patient (ISMP, 2015, p. 12).
- If the IV is a small gauge (22 to 24 gauge) placed in a small vein, a blood return may not occur even if the IV is intact. Also, the patient may report stinging and pain at the site while medication is being administered due to irritation of the vein. Slowing the rate of administration may relieve discomfort.
- Ongoing assessment is an important part of nursing care for both evaluation of patient response to administered medications and early detection of adverse drug reactions. If an adverse effect is suspected, withhold further medication doses and notify the health care team. Additional intervention is based on type of reaction and patient assessment.

Skill 30-9 Administering Medications by Intravenous Bolus or Push Through a Medication or Drug-Infusion Lock

DELEGATION CONSIDERATIONS

The administration of medications through an intermittent peripheral venous access device is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the administration of specified IV medications in some settings may be delegated to licensed practical/vocational nurses (LPN/LVNs) who have received appropriate training. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.



Equipment

- Prescribed medication
- Two normal saline flushes prepared in a syringe (3 to 10 mL) according to facility policy
- Antimicrobial swabs
- Passive disinfection caps (based on facility policy)
- Syringe with a needleless device or 23- to 25-gauge, 1-inch needle (follow facility policy)
- Watch or clock with a second hand
- Disposable gloves
- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)
- Additional PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in place. Clarify any inconsistencies. Check the patient's health record for allergies. Check a drug resource to clarify whether medication needs to be	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

diluted before bolus administration. Verify the recommended administration rate.	located in a health care facility and to outpatient pharmacies. Recommended administration rate delivers the correct dose of medication as prescribed.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and adverse effects of the medications to be administered. Consider the appropriateness of the medication for this patient.	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication.
	Hand hygiene prevents the spread of microorganisms.
3. Perform hand hygiene.	
4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode and scan employee identification, if required.	Locking the medication supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized users into the system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.
7. Read the eMAR/MAR and select the proper medication from the medication supply system or the patient's medication drawer.	This is the *first* check of the label.
8. Compare the label with the eMAR/MAR. Check expiration dates and perform calculations, if necessary. Scan the bar code on the package, if required.	This is the *second* check of the label. Verify calculations with another nurse to ensure safety, if necessary.
9. If necessary, withdraw the medication from an ampule or vial as described in Skills 30-2 and 30-3.	Allows administration of medication.
10. **Depending on facility policy, the third check of the label may occur at this point. If so, when all medications for one patient have been prepared, recheck the labels with the eMAR/MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**	This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration.
11. Label the syringe with the medication's name, dose, and amount (The Joint Commission, 2021).	Unlabeled syringes are unidentifiable and may lead to a medication administration error (The Joint Commission, 2021).
12. **Log out of and/or lock the medication supply system before leaving it.**	Locking the medication supply system or drawer safeguards the patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use.
13. Transport medications and equipment to the patient's bedside carefully and keep the medications in sight at all times.	Careful handling and close observation prevent accidental or deliberate disarrangement of medications. Having equipment available saves time and facilitates performance of the task.
14. **Ensure that the patient receives the medications at the correct time.**	Check facility policy, which may allow for administration within a period of 30 minutes before or 30 minutes after the designated time.
	Hand hygiene and PPE prevent the spread of

 15. Perform hand hygiene and put on PPE, if indicated.	microorganisms. PPE is required based on transmission precautions.
 16. **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two of the following methods** (The Joint Commission, 2021): a. Check the name on the patient's identification band. b. Check the identification number on the patient's identification band. c. Check the birth date on the patient's identification band. d. Ask the patient to state their name and birth date, based on facility policy.	Identifying the patient ensures the right patient receives the medications and helps prevent errors. The patient's room number or physical location is not used as an identifier (The Joint Commission, 2021). Replace the identification band if it is missing or inaccurate in any way. This requires a response from the patient, but illness and strange surroundings often cause patients to be confused.
17. Close the door to the room or pull the bedside curtain.	This provides patient privacy.
18. **Complete necessary assessments before administering medications. Check the patient's allergy bracelet, if present, or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**	Assessment is a prerequisite to administration of medications. Explanation provides rationale, increases knowledge, and reduces anxiety.
19. Scan the bar code on the patient's identification band, if required (The Joint Commission, 2021) (Figure 1).	Scanning provides an additional check to ensure that the medication is given to the right patient.

FIGURE 1. Scanning bar code on patient's identification bracelet.

20. **Based on facility policy, the third check of the label may occur at this point. If so, recheck the labels with the eMAR/MAR before administering the medications to the patient.**	Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration. If facility policy directs the *third* check at this time, this *third* check ensures accuracy and helps to prevent errors.
21. Assess the IV site for the presence of inflammation or infiltration.	IV medication must be given directly into a vein for safe administration.
22. Put on gloves.	Gloves protect the nurse's hands from contact with the patient's blood.
23. Remove the passive disinfection cap from the needleless connector or access port of the medication	Passive disinfection caps contain an antiseptic-impregnated sponge that dispenses the antiseptic

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

lock (Figure 2). Alternatively, if a passive disinfection cap is not in place, use an antimicrobial swab to vigorously disinfect the connection surface and sides of the needleless connector or end cap on the injection port and allow it to dry.	over the connector's top and threads and protects the hub from contamination by touch or airborne sources (Barton, 2019; Casey et al., 2018). Venous access device entry points, end caps, and needleless connectors must be vigorously scrubbed and disinfected prior to each access to reduce the risk for introduction of microorganisms and prevent venous access device–related infection (Flynn et al., 2019; Gorski et al., 2021). Friction is needed to physically remove microorganisms from the top, sides, and threads of the needleless connector or end cap. Allow the antiseptic to dry completely to ensure complete effectiveness (Gorski et al., 2021; Slater et al., 2018).
24. Uncap the saline flush syringe. Stabilize the port with your nondominant hand and insert the saline flush syringe into the needleless connector or end cap on the access port of the medication lock (Figure 3).	Assessing patency of the venous access device is necessary to ensure IV administration of the medication.
25. Release the clamp on the extension tubing of the medication lock (Figure 4). Pull back on the syringe plunger to aspirate the catheter for positive blood return (Figure 5). If positive, instill the solution over 1 minute or according to facility policy. Observe the insertion site while inserting the saline. Remove the syringe.	Positive blood return confirms patency before administration of medications and solutions (Gorski et al., 2021). Flushing without incident ensures patency of the IV line and administration of the medication into the bloodstream. Puffiness, pain, or swelling as the site is flushed could indicate infiltration of the catheter.

FIGURE 2. Removing the passive disinfection cap from the access port.

FIGURE 3. Inserting the saline flush syringe into the access port.

FIGURE 4. Releasing the clamp on the extension tubing.

FIGURE 5. Pulling back on the plunger to aspirate for a blood return.

26. Use an antimicrobial swab to vigorously disinfect the connection surface and sides of the needleless connector or end cap on the injection port and allow it to dry.	Venous access device entry points, end caps, and needleless connectors must be vigorously scrubbed and disinfected prior to each access to reduce the risk for introduction of microorganisms and prevent venous access device–related infection (Flynn et al., 2019; Gorski et al., 2021). Friction is needed to

	physically remove microorganisms from the top, sides, and threads of the needleless connector or end cap. Allow the antiseptic to dry completely to ensure complete effectiveness (Gorski et al., 2021; Slater et al., 2018).
27. Uncap the medication syringe. Insert the medication syringe into the needleless connector or end cap on the access port of the medication lock. Using a watch or clock with a second-hand to time the rate, **inject the medication at the recommended rate (Figure 6). Do not force the injection if resistance is felt.**	This delivers the correct amount of medication at the proper interval. Easy installation of medication usually indicates that the lock is still patent and in the vein. If force is used against resistance, a clot may break away and cause a blockage elsewhere in the body.
28. While administering the medication, observe the infusion site and assess the patient for any adverse reaction. If signs of adverse reaction occur, stop the infusion immediately and notify the health care team.	Signs of adverse reaction, such as peripheral IV infiltration, rash or itching, or pain at the infusion site, necessitate stopping administration of the drug (Gorski et al., 2021).
29. Remove the medication syringe from the access port. Use a new antimicrobial swab to vigorously disinfect the connection surface and sides of the needleless connector or end cap on the injection port and allow it to dry. Stabilize the port with your nondominant hand. Uncap the second saline flush syringe. Insert the saline flush syringe into the needleless connector or end cap on the access port. Instill the flush solution at the same rate as the administered medication (Gorski et al., 2021).	Venous access device entry points, end caps, and needleless connectors must be vigorously scrubbed and disinfected prior to each access to reduce the risk for introduction of microorganisms and prevent venous access device–related infection (Flynn et al., 2019; Gorski et al., 2021). Friction is needed to physically remove microorganisms from the top, sides, and threads of the needleless connector or end cap. Allow the antiseptic to dry completely to ensure complete effectiveness (Gorski et al., 2021; Slater et al., 2018). Flushing after medication administration ensures the entire drug dose has been cleared from the extension tubing on the venous access device or from the infusion system and prevents precipitation due to solution/medication incompatibility (Gorski et al., 2021).
30. If the medication lock is capped with a positive pressure valve/device, remove the syringe, and then clamp the extension tubing (Figure 7). Alternatively, to gain positive pressure if positive pressure valve/device is not present, clamp the extension tubing as you are still flushing the last of the saline into the medication lock. Remove the syringe.	Positive pressure prevents blood from backing into the catheter and causing the medication lock to clot off.

FIGURE 6. Injecting the medication at the recommended rate.

FIGURE 7. Clamping the extension tubing.

31. Using an antimicrobial swab, vigorously disinfect the connection surface and sides of the needleless connector or end cap on the injection port and allow it to dry. Attach a passive disinfection cap to the needleless connector or end cap on the access port of the medication lock (Figure 8).	Venous access device entry points, end caps, and needleless connectors must be vigorously scrubbed and disinfected prior to each access to reduce the risk for introduction of microorganisms and prevent venous access device–related infection (Flynn et al., 2019; Gorski et al., 2021). Friction is needed to

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

physically remove microorganisms from the top, sides, and threads of the needleless connector or end cap. Allow the antiseptic to dry completely to ensure complete effectiveness (Gorski et al., 2021; Slater et al., 2018). Passive disinfection caps contain an antiseptic-impregnated sponge that dispenses the antiseptic over the connector's top and threads and protect the hub from contamination by touch or airborne sources (Barton, 2019; Casey et al., 2018).

FIGURE 8. Attaching a passive disinfection cap to the access port.

32. Discard the syringe in the appropriate receptacle.	Proper disposal prevents injury and the spread of microorganisms.
33. Remove gloves and additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk of infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
34. Document the administration of the medication immediately after administration. See Documentation section below.	Timely documentation helps to ensure patient safety.
35. Evaluate the patient's response to the medication within an appropriate time frame.	The patient needs to be evaluated for therapeutic and adverse effects from the medication.

DOCUMENTATION

Guidelines

Document the administration of the medication and saline flush, including date, time, dose, route of administration, site of administration, and rate of administration on the eMAR/MAR or record using the required format, immediately after administration. If using a bar-code system, medication administration is automatically recorded when the bar code is scanned. PRN medications require documentation of the reason for administration. Prompt recording avoids the possibility of accidentally repeating the administration of the drug. If the drug was refused or omitted, record this in the appropriate area on the medication record and notify the health care team as appropriate. This verifies the reason medication was omitted and ensures that the health care personnel providing care for the patient are aware of the occurrence.

Developing Clinical Reasoning and Clinical Judgment

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Upon assessing the medication lock site before administering the medication, you note that the medication lock has infiltrated:* Remove the medication lock from the extremity. Restart the peripheral venous access in a different location. Continue to monitor the new site as the medication is administered.
- *While you are administering medication, the patient begins to complain of pain at the site:* Stop the medication. Assess the medication lock site for signs of infiltration and phlebitis. Flush the medication lock with normal saline

again to recheck patency. If the IV site appears within normal limits, resume medication administration at a slower rate. If pain persists, stop, remove the medication lock, and restart in a different location.

- *As you are attempting to access the lock, the syringe tip touches the patient's arm:* Discard the syringe. Prepare a new dose for administration.
- *No blood return is noted upon aspiration:* If the medication lock appears patent, without signs of infiltration, and normal saline fluid infuses without difficulty, proceed with administration. Observe closely for signs and symptoms of infiltration during and after administration.

SPECIAL CONSIDERATIONS

General Considerations

- Vascular access devices should also be "locked" after completion of the flush solution at each use to decrease the risk of occlusion and catheter-related bloodstream infection (Gorski et al., 2021). According to the guidelines from the INS, vascular access devices are locked with normal saline solution (Gorski et al., 2021). If the device is not in use, periodic flushing according to facility policy is required to keep the catheter patent.
- Previously, recommendations suggested routine rotation of insertions sites at various intervals, usually 72 to 96 hours. Current research and guidelines support maintaining peripheral IV access devices until no longer clinically indicated or until a complication develops (Gorski et al., 2021; Weston, 2019). Nurses should use clinical assessment and judgment in deciding when to replace or discontinue a peripheral venous access device.
- The clinical need for the IV catheter should be assessed on a daily basis (Gorski et al., 2021). The device insertion site and dressing should be assessed every 4 hours at a minimum (Gorski et al., 2021; Weston, 2019).
- A peripheral venous access device that is no longer necessary should not be kept in place just in case it may be needed in a few days (Weston, 2019).
- Ongoing assessment is an important part of nursing care to evaluate patient response to administered medications and early detection of adverse reactions. If an adverse effect is suspected, withhold further medication doses and notify the health care team. Additional intervention is based on type of reaction and patient assessment.

Infant and Child Considerations

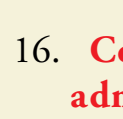
- The primary method for IV medication administration for infants and children is a mini-infusion (syringe) pump (Kyle & Carman, 2021). Refer to Skill 30-10.
- Administration of IV bolus or push medication is usually reserved for emergency situations and when therapeutic blood levels must be reached quickly to achieve the desired effect (Kyle & Carman, 2021).

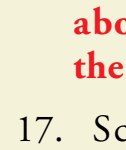
Skill 30-10 Administering a Piggyback Intermittent Intravenous Infusion of Medication

DELEGATION CONSIDERATIONS

The administration of medications by intermittent IV infusion is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the administration of specified IV medications in some settings may be delegated to licensed practical/vocational nurses (LPN/LVNs) who have received appropriate training. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT





- Medication prepared in labeled small-volume IV bag
- Short secondary infusion tubing
- Infusion pump
- Antimicrobial swab
- Needleless connector, if required, based on facility procedure
- Metal or plastic hook
- IV pole
- Watch or clock with a second hand (gravity infusion)
- Date label for tubing

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Electronic Medication Administration Record (eMAR) or Medication Administration Record (MAR)
- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check each medication prescribed against the original in the health record, depending on facility policy and the medication order system in place. Clarify any inconsistencies. Check the patient's health record for allergies. Check the administration rate.	The prescription is the legal record of prescribed medication interventions. This comparison helps to identify errors that may have occurred when orders were transcribed. Computer provider order-entry (CPOE) systems allow prescribers to send electronic medication prescriptions directly to the pharmacy located in a health care facility and to outpatient pharmacies.
2. Know the actions, special nursing considerations, safe dose ranges, purpose of administration, and adverse effects of the medications to be administered. Consider the appropriateness of the medication for this patient. **Assess the compatibility of the ordered medication, diluent, and the infusing IV fluid.**	This knowledge aids the nurse in evaluating the therapeutic effect of the medication in relation to the patient's health status and can also be used to educate the patient about the medication. Compatibility of medication and solutions prevents complications.
	Hand hygiene prevents the spread of microorganisms.
3. Perform hand hygiene.	
4. Move the medication supply system to the outside of the patient's room or prepare for administration at the medication supply system in the medication area. Alternatively, access the medication administration supply system at or inside the patient's room.	Organization facilitates error-free administration and saves time.
5. Unlock the medication supply system or drawer. Enter the passcode and scan employee identification, if required.	Locking the medication supply system or drawer safeguards each patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use. Entering the passcode and scanning ID allows only authorized users into the system and identifies the user for documentation by the computer.
6. **Prepare medications for one patient at a time.**	This prevents errors in medication administration.
7. Read the eMAR/MAR and read the label when selecting the proper medication from the medication supply system or the patient's medication drawer.	This is the *first* check of the label.
8. Read the label and compare the label with the eMAR/MAR. Check expiration dates. Confirm the prescribed or appropriate infusion rate. Calculate the drip rate if using a gravity system. Scan the bar code on the package, if required.	This is the *second* check of the label. Verify calculations with another nurse to ensure safety, if necessary. Infusing medication at an appropriate rate prevents injury.
9. **Depending on facility policy, the third check of the label may occur at this point. If so, when all medications for one patient have been prepared, read the label and recheck the labels with the eMAR/MAR before taking the medications to the patient. However, many facilities require the third check to occur at the bedside, after identifying the patient.**	This *third* check ensures accuracy and helps to prevent errors. *Note:* Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration.
10. **Log-out of and/or lock the medication supply system before leaving it.**	Locking the medication supply system or drawer safeguards the patient's medication supply. Facility accrediting organizations require medication supply systems to be locked when not in use.

11. Transport medications to the patient's bedside carefully and keep the medications in sight at all times.	Careful handling and close observation prevent accidental or deliberate disarrangement of medications.
12. **Ensure that the patient receives the medications at the correct time.**	Check facility policy, which may allow for administration within a period of 30 minutes before or 30 minutes after the designated time.
 13. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 14. **Identify the patient. Compare the information with the eMAR/MAR. The patient should be identified using at least two of the following methods** (The Joint Commission, 2021): a. Check the name on the patient's identification band. b. Check the identification number on the patient's identification band. c. Check the birth date on the patient's identification band. d. Ask the patient to state their name and birth date, based on facility policy.	Identifying the patient ensures the right patient receives the medications and helps prevent errors. The patient's room number or physical location is not used as an identifier (The Joint Commission, 2021). Replace the identification band if it is missing or inaccurate in any way. This requires a response from the patient, but illness and strange surroundings often cause patients to be confused.
15. Close the door to the room or pull the bedside curtain.	This provides patient privacy.
16. **Complete necessary assessments before administering medications. Check the patient's allergy bracelet, if present, or ask the patient about allergies. Explain the purpose and action of the medication to the patient.**	Assessment is a prerequisite to administration of medications. Explanation provides rationale, increases knowledge, and reduces anxiety.
17. Scan the patient's bar code on the identification band, if required (The Joint Commission, 2021).	Scanning provides an additional check to ensure that the medication is given to the right patient.
18. **Based on facility policy, the third check of the label may occur at this point. If so, read the label and recheck the labels with the eMAR/MAR before administering the medications to the patient.**	Many facilities require the *third* check to occur at the bedside, after identifying the patient and before administration. If facility policy directs the *third* check at this time, this *third* check ensures accuracy and helps to prevent errors.
19. Assess the IV site for the presence of inflammation or infiltration or other signs of complications.	IV medication must be given directly into a vein for safe administration.
20. Close the clamp on the short secondary infusion tubing. Using aseptic technique, remove the cap on the tubing spike and the cap on the port of the medication container, taking care to avoid contaminating either end.	Closing the clamp prevents fluid from entering the system until the nurse is ready. Maintaining sterility of the tubing and the medication port prevents contamination.
21. Attach the infusion tubing to the medication container by inserting the tubing spike into the port with a firm push and twisting motion, taking care to avoid contaminating either end.	Maintaining sterility of the tubing and medication port prevents contamination.
22. Hang the piggyback container on the IV pole, positioning it higher than the primary IV if necessary, based on the type of IV infusion device in use and according to the manufacturer's	The position of the containers influences the flow of IV fluid into the primary setup.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

recommendations. If necessary for the particular infusion pump in use, use the metal or plastic hook to lower the primary IV fluid container (Figure 1). If using gravity infusion, the primary IV fluid container must be lowered.	
23. If the secondary infusion tubing is being used for the first time, place a label on the administration tubing with the current date.	Most facilities allow the reuse of tubing, reducing the risk for contamination. The frequency of administration set tubing changes varies. The label identifies the date of the first use of the tubing. Intermittent administration sets disconnected after use should be replaced every 24 hours; repeated disconnection and reconnection increase the risk of contamination at the spike end, catheter hub, needleless connector, and the end of the administration set, potentially increasing the risk for catheter-related bloodstream infection (Gorski et al., 2021)
24. Squeeze the drip chamber on the administration tubing and release. Fill the chamber to the line or about half full. Open the clamp on the administration tubing and prime the tubing. Close the clamp. Place the needleless connector on the end of the tubing, using sterile technique, if required.	This removes air from tubing and preserves the sterility of the setup.
25. Remove the passive disinfection cap from the needleless connector or end cap on the infusion set injection port. Alternatively, if a passive disinfection cap is not in place, use an antimicrobial swab to vigorously disinfect the connection surfaces and sides of the access port or stopcock on the administration set above where the tubing enters the infusion pump or above the roller clamp on the primary IV infusion tubing (gravity infusion) (Figure 2).	Passive disinfection caps contain an antiseptic-impregnated sponge that dispenses the antiseptic over the connector's top and threads and protects the hub from contamination by touch or airborne sources (Barton, 2019; Casey et al., 2018). Venous access device entry points, end caps, and needleless connectors must be vigorously scrubbed and disinfected prior to each access to reduce the risk for introduction of microorganisms and prevent venous access device–related infection (Flynn et al., 2019; Gorski et al., 2021). Friction is needed to physically remove microorganisms from the top, sides, and threads of the needleless connector or end cap. Allow the antiseptic to dry completely to ensure complete effectiveness (Gorski et al., 2021; Slater et al., 2018).The backflow valve in the primary line secondary port stops flow of the primary infusion while the piggyback solution is infusing. Once completed, the backflow valve opens, and flow of the primary solution resumes.

FIGURE 1. Lowering the primary IV fluid container to position the piggyback container higher than primary IV fluid container. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

FIGURE 2. Vigorously scrubbing the access port. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

26. Connect the piggyback setup to the access port	Needleless systems and a stopcock setup eliminate the

(Figure 3) or stopcock. If using, turn the stopcock to the open position.

FIGURE 3. Connecting piggyback administration set to access port. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

27. Alternatively, if the administration set is in place from a previous infusion, there is no need to disconnect the secondary tubing to connect the current dose of medication. The secondary tubing will be primed via "backfill" or "back prime" of the secondary tubing.	Most facilities allow the reuse of tubing, reducing the risk for contamination. "Back prime" is recommended as the method to use to prime a secondary administration set when there is compatibility with the primary fluid (Gorski et al., 2021). The frequency of administration set tubing changes varies.
28. Clamp the secondary infusion tubing and remove the previous, empty medication bag. Attach the current medication dose bag to the secondary infusion tubing, as outlined in Steps 20–22. Lower the medication bag below the main IV solution container and open the clamp on the secondary infusion tubing. This allows the primary IV solution to flow up the secondary tubing to the drip chamber, "back priming" or "backfilling" the tubing. Allow the solution to enter the drip chamber until the drip chamber is half full. Close the clamp on the secondary tubing and hang the medication container on the IV pole.	This "backfill" method keeps the infusion system intact, preventing both introduction of microorganisms and loss of medication when the tubing is primed. "Back prime" is recommended as the method to use to prime a secondary administration set when there is compatibility with the primary fluid (Gorski et al., 2021). Check facility policy regarding the use of "back prime."
29. Open the clamp on the secondary infusion tubing. Set the rate for the secondary infusion on the infusion pump and begin the infusion (Figure 4). If using gravity infusion, use the roller clamp on the primary infusion tubing to regulate the flow at the prescribed delivery rate (Figure 5). Monitor medication infusion at periodic intervals.	The backflow valve in the primary line secondary port stops the flow of the primary infusion while the piggyback solution is infusing. Once completed, the backflow valve opens, and flow of the primary solution resumes. It is important to verify the safe administration rate for each drug to prevent adverse effects.

FIGURE 5. Using roller clamp on primary infusion tubing to regulate gravity flow. (*Source:* Used with permission

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

from Shutterstock. *Photo by B. Proud.*)

30. Clamp the tubing on the piggyback set when the solution is infused and leave the setup in place.	Most facilities allow the reuse of tubing, reducing the risk for contamination. Leaving the secondary tubing and medication bag in place until the next dose keeps the infusion system intact, preventing both introduction of microorganisms and loss of medication when the tubing is primed. "Back prime" is recommended as the method to use to prime a secondary administration set when there is compatibility with the primary fluid (Gorski et al., 2021). Check facility policy regarding the use of "back prime." The frequency of administration set tubing changes varies.
31. Raise the primary IV fluid container to the original height, if lowered for the infusion. **Check the primary infusion rate on the infusion pump. If using gravity infusion, readjust the flow rate of the primary IV.**	Most infusion pumps automatically restart the primary infusion at the previous rate after the secondary infusion is completed. If using gravity infusion, piggyback medication administration may interrupt the normal flow rate of the primary IV. Rate readjustment may be necessary.
 32. Remove PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk of infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
33. Document the administration of the medication immediately after administration. See Documentation section below. Document the volume of fluid administered on the intake and output record, if necessary.	Timely documentation helps to ensure patient safety.
34. Evaluate the patient's response to the medication within an appropriate time frame.	The patient needs to be evaluated for therapeutic and adverse effects from the medication.

DOCUMENTATION

Guidelines

Document the administration of the medication immediately after administration, including date, time, dose, route of administration, site of administration, and rate of administration on the eMAR/MAR or record using the required format. If using a bar-code system, medication administration is automatically recorded when the bar code is scanned. PRN medications require documentation of the reason for administration. Prompt recording avoids the possibility of accidentally repeating the administration of the drug. If the drug was refused or omitted, record this in the appropriate area on the medication record and notify the health care team as appropriate. This verifies the reason medication was omitted and ensures that health care personnel providing care for the patient are aware of the occurrence. Document the volume of fluid administered on the intake and output record.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Upon assessing the IV site before administering medication, you note that the IV has infiltrated:* Stop the IV fluid and remove the IV from the extremity. Restart the IV in a different location. Continue to monitor the new IV site as the medication is administered.
- *While administering medication, you note a cloudy, white substance forming in the IV tubing:* Stop the IV from flowing and stop administering the medication to prevent precipitate from entering the patient's circulation. Clamp the IV at the site nearest to the patient. Replace tubing on primary and secondary infusions. Check a drug resource or consult a pharmacist regarding compatibility of the medication and IV fluid before continuing with administration. Medication infusion may require a second IV site or administration through an access port closer to the IV site and flushing of the tubing before and after administration.
- *While you are administering medication, the patient begins to complain of pain at the IV site:* Stop the medication. Assess the IV site for any signs of complications. Flush the IV with normal saline to check for patency. If the IV site appears within normal limits, resume medication administration at a slower rate.

SPECIAL CONSIDERATIONS

General Considerations

- Intermittent administration sets disconnected after use should be replaced every 24 hours; repeated disconnection and reconnection increases risk of contamination at the spike end, catheter hub, needleless connector, and the end of the administration set, potentially increasing the risk for catheter-related bloodstream infection (Gorski et al., 2021).
- Ongoing assessment is an important part of nursing care for both evaluation of patient response to administered medications and early detection of adverse reactions. If an adverse effect is suspected, withhold further medication doses and notify the patient's health care team. Additional intervention is based on type of reaction and patient assessment.

Infant and Child Considerations

- The primary method for IV medication administration for infants and children is a mini-infusion (syringe) pump (Kyle & Carman, 2021).
- Infants and small children with fluid restrictions may not tolerate the added IV fluid needed for administration with piggyback systems. For these children, consider using the mini-infusion pump.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. See the accompanying Nursing Care Plan for Regina Sauder for an example of the nursing process for medication administration.

. You are scheduled to give an intramuscular injection in the ventrogluteal site and remember learning that it should be administered using the Z-track technique. When you mention this to the nurse in the hospital who has been taking care of your patient, she tells you there is no reason to use the Z-track technique. You remember your instructor telling you to use the Z-track technique. What should you do?

. You are caring for two patients and have just completed giving medications to the first when you realize that you gave her the medications prescribed for your other patient. What should you do?

PRACTICING FOR NCLEX

. A nurse administers a dose of an oral medication for hypertension to a patient who immediately vomits after swallowing the pill. What action will the nurse take first?

a. Readminister the medication and notify the health care provider.
b. Obtain the pill in a liquid form for administration.
c. Assess the emesis, looking for the pill.
d. Notify the primary care provider.

. A nurse caring for a group of patients uses measures to reduce discomfort for the patients during injections. Which technique is recommended?

a. Selecting a needle of the largest gauge that is appropriate for the site and solution to be injected
b. Injecting the medication into contracted muscles to reduce pressure and discomfort at the site
c. Using the Z-track technique for intramuscular injections to prevent leakage of medication into the needle track
d. Applying vigorous pressure in a circular motion after the injection to distribute the medication to the intended site

. A nurse is preparing medications for patients in the ICU. The nurse is aware that patient variables may affect the absorption of these medications. Which statements accurately describe these variables the nurse will use as a basis for practice? Select all that apply.

a. Patients in certain ethnic groups obtain therapeutic responses at lower doses or higher doses than those usually prescribed.
b. Some people experience the same response with a placebo as with the active drug used in studies.
c. People with liver disease metabolize drugs more quickly than people with normal liver functioning.
d. A patient who receives a pain medication in a noisy environment may not receive full benefit from the medication's effects.
e. Oral medications should not be given with food as the food may delay the absorption of the medications.
f. Circadian rhythms and cycles may influence drug action.

. A nurse is administering a pain medication to a patient. In addition to checking the identification bracelet, which active identification strategy reflects best practice?

a. Asking the patient their name and birthdate

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

b. Reading the patient's name on the sign over the bed
c. Asking the patient's roommate to verify the patient's name
d. Asking, "Are you Mr. Brown?"

. A nurse is administering a medication to a patient via an enteral feeding tube. Which are accurate guidelines related to this procedure? Select all that apply.
a. Crushing the enteric-coated pill and mix it in a liquid
b. Initially flushing the tube with 60 mL of very warm water
c. Using the recommended policy to check tube placement in the stomach or intestine
d. Giving each medication separately and flush with water between each drug
e. Lowering the head of the bed to prevent reflux
f. Adjusting the amount of water used if patient's fluid intake is restricted

. A medication prescription reads: "Hydromorphone, 2 mg IV every 3 to 4 hours PRN pain." The prefilled cartridge is available with a label reading "Hydromorphone 2 mg/1 mL" and a statement that the cartridge contains 1.2 mL of hydromorphone. How should the nurse proceed?
a. Give the entire contents of the cartridge sent by the pharmacy
b. Call the pharmacy and request the proper dose
c. Refuse to give the medication and document refusal in the EHR
d. Discard 0.2 mL before administration; verify the waste with another nurse

. A nurse prepares to administer insulin to a patient with diabetes. What is the correct procedure to carry out this prescription?
MAR
7:30 AM: 40 units of NPH insulin and 10 units of regular insulin daily subcutaneously.
a. Inject air into the regular insulin vial and withdraw 10 units; then, using the same syringe, inject air into the NPH vial and withdraw 40 units of NPH insulin.
b. Inject air into the NPH insulin vial, being careful not to allow the solution to touch the needle; next, inject air into the regular insulin vial and withdraw 10 units; followed by withdrawal of 40 units of NPH insulin.
c. Inject air into the regular insulin vial, being careful not to allow the solution to touch the needle; next, inject air into the NPH insulin vial and withdraw 40 units; then, withdraw 10 units of regular insulin.
d. Inject air into the NPH insulin vial and withdraw 40 units; then, using the same syringe, inject air into the regular insulin vial and withdraw 10 units of regular insulin.

. A nurse is administering heparin subcutaneously to a patient. What technique is appropriate for this injection?
a. Aspirating before giving and gently massage after the injection
b. Avoiding aspirating; massaging the site for 1 minute
c. Avoiding aspirating before and massaging after the injection
d. Massaging the injection site; aspirating is unnecessary but will do no harm

. A nurse discovers that a medication error occurred. What is the nurse's priority?
a. Recording the error on the medication sheet
b. Notifying the physician regarding course of action
c. Assessing the patient for adverse effects of the error
d. Completing an event report, explaining how the mistake was made

. A nurse is teaching a patient how to use a meter-dosed inhaler to control asthma. What are appropriate guidelines for this procedure? Select all that apply.
a. Shake the inhaler well and remove the mouthpiece covers from the MDI and spacer.
b. Take shallow breaths when breathing through the spacer.
c. Depress the canister releasing one puff into the spacer and inhale slowly and deeply.
d. After inhaling, exhale quickly through pursed lips.
e. Wait 1 to 5 minutes as prescribed before administering the next puff.
f. Gargle and rinse with salt water after using the MDI.

. A nurse in a rehabilitation facility is preparing to administer a skeletal muscle relaxant to a patient recovering from a motor vehicle accident. When the patient states, "I don't want that pill," what action will the nurse take next?
a. Encourage the patient to take the pill to help reduce muscle spasm.
b. Explain that the health care provider prescribes only necessary medications.
c. Ask the patient to explain their concern about the medication.
d. Question the patient about allergies and previous medication reactions.

. A nurse is preparing to administer medications to a patient transferred from the intensive care unit just as lunch is served. Prior to administering medications to the patient, the nurse takes which action?

a. Performing medication reconciliation
b. morning care has been administered
c. Ordering the patient a meal
d. Taking a report from the nurse sending the patient

. When administering an IVPB medication using gravity, what action is appropriate for the nurse take?

a. Placing the primary IV bag below the level of the piggyback bag
b. Disconnecting the tubing closest to the patient and flushing the intravenous access
c. Ensuring the piggyback bag is below the main IV bag
d. Closing the roller clamp to the secondary infusion

. A nurse is administering enoxaparin subcutaneously using the manufacturer's prefilled syringe. Which action reflects correct practice?

a. Administering the medication in the posterolateral abdomen
b. Removing air bubble prior to injecting
c. Gently rubbing the abdomen after injection to promote absorption
d. Replacing the cap on the syringe before discarding it in the sharps container

. A nurse is administering medications to an older adult with dysphagia. After crushing the pills, which action is most appropriate?

a. Mixing the crushed medications with 120 mL of water before administering
b. Mixing the medications into the patient's bowl of pudding
c. Crushing each pill separately and administering each in a teaspoon of applesauce
d. Asking the patient to chew the pills and providing juice after swallowing

. A patient experiencing chest pain asks the nurse why a nitroglycerin tablet must be placed under their tongue instead of swallowed. Which answer by the nurse is appropriate?

a. "We could put the tablet between the cheek and gum, instead."
b. "The area is rich in superficial blood vessels, and helps with absorption."
c. "Swallowing interferes with quick systemic effects."
d. "This is an enteric-coated tablet, designed for absorption outside the stomach."

. A nurse in the pediatric unit of an acute care hospital is awaiting a prescription for antibiotics for a toddler with a severe infection. Which information about the child is essential to document immediately?

a. Beverage preference
b. Whether a parent/guardian is present at the bedside
c. Weight in kilograms
d. Intake and output

. A nurse in a pediatric practice teaches the mother of a toddler to administer antibiotic ear drops. What education by the nurse is correct?

a. "It is best to pull the pinna of the affected ear up and back."
b. "Place the child on their side of the affected ear and pull the pinna straight back."
c. "When administering the ear drop, gently pull the pinna down and back."
d. "Cleanse the ear canal with a cotton swab before administering."

. A nurse is planning to administer digoxin to a patient. After reviewing the medical record, what action will the nurse take?
Electronic Health Record
Prescriptions

- 11/22/2025 digoxin loading dose 0.25 mg IV twice today only
- 11/23/2025 begin digoxin 0.125 mg orally daily
  Laboratory Studies
- Digoxin level: 2.7 ng/mL (reference range 0.5–2 ng/mL)

a. Administer the medication, recording the level in the MAR.
b. Hold the medication and confer with the prescriber.
c. Give the patient one half the dose.
d. Evaluate the patient's kidney function studies.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

. A nurse notices that an older adult patient is malnourished, and blood tests reveal reduced plasma protein levels. For which of these pharmacodynamic effects will the nurse observe?

a. Medication toxicities
b. Failure to thrive
c. Weight gain
d. Mental confusion

. A nurse on a medical-surgical unit is planning to administer an antibiotic to a patient with a kidney infection who is 10 weeks' pregnant. The drug reference states that the medication is teratogenic. Which action will the nurse take?

a. Administer the medication, because the risk of illness is greater than the benefit of the medication.
b. Hold the medication and collaborate with the health care provider to find an alternative.
c. Ask the patient if they consent to receive the medication and document the response in the electronic health record.
d. Collaborate with the pharmacist on dose reduction.

. At 8 AM, a nurse receives a prescription for an analgesic to be administered every 4 hours PRN. The nurse plans to administer this medication at what times?

a. 0800, 1200, 1600, 2000, 0000, 0400 hours
b. Around the clock on even hours
c. Six times daily
d. Upon patient request, within prescribed time intervals

ANSWERS WITH RATIONALES

. **c**. If a patient vomits immediately after swallowing an oral pill, the nurse should assess the emesis (vomit) for the pill or fragments of it. The nurse will collaborate with the health care provider to determine if another dose should be administered.

. **c**. The nurse should use the Z-track technique for intramuscular injections to prevent medication from leaking into the needle track, minimizing discomfort. The nurse should select a needle of the smallest gauge that is appropriate for the site and solution to be injected, and select the correct needle length for the type of injection and patient size. The nurse should inject the medication into relaxed muscles since more pressure (causing discomfort) will be required to injected into contracted muscles. The nurse should apply gentle pressure after injection, unless this technique is contraindicated.

. **a, b, d, f**. Nurses are responsible for applying pharmacologic knowledge during medication administration, including varied responses in patients from different ethnic groups (ethnopharmacology). The patient's expectations of the medication may affect the response to the medication; for example, when a placebo is given and a patient has a therapeutic effect. Environment may also influence the patient's response to medications; for example, sensory deprivation and overload may affect drug responses. Circadian rhythms and cycles may also influence drug action. The liver is the primary organ for drug breakdown, thus pathologic conditions that involve the liver may slow metabolism and alter the dosage of the drug needed to reach a therapeutic level. The presence of food in the stomach can delay the absorption of orally administered medications. Alternatively, some medications should be given with food to prevent gastric irritation, which the nurse should consider when establishing a patient's medication schedule. Other medications may have enhanced absorption if taken with certain foods.

. **a.** The nurse should ask the patient to state their name and birthdate based on facility policy. A sign over the patient's bed may not be current or correct. The roommate is an unsafe source of information. The patient may not hear their name or may reply in the affirmative regardless of accuracy (e.g., a person with a hearing deficit).

. **c, d, f**. The nurse should use the facility policy for checking tube placement prior to administering medications. The nurse should also give each medication separately and flush with water between each drug, adjusting the amount of water used if fluids are restricted. Enteric-coated medications should not be crushed, the tube should be flushed with 15 to 30 mL of water, and the head of the bed should be elevated to prevent reflux and aspiration.

. **d**. Many prefilled medication cartridges are overfilled, requiring some medication to be discarded to prevent adverse effects. Always check correct dose compared to the volume in the syringe for accuracy. As this is a prefilled syringe, it is not necessary to call the pharmacy or refuse to give the medication. Wasting narcotics typically requires a second RN to witness the waste and verify the amount of narcotic discarded.

. **b**. Regular or short-acting insulin (unmodified insulin) should never be contaminated with NPH or any insulin modified with added protein. Placing air in the NPH vial first without allowing the needle to contact the solution ensures that the regular insulin will not be contaminated.

. **c**. When giving heparin subcutaneously, the nurse should not aspirate or massage, so as not to cause trauma or bleeding in the tissues.

. **c**. The nurse's first responsibility is the patient—careful observation is necessary to assess for adverse effects of the medication error. The other nursing actions are pertinent but only after evaluating the patient's welfare.

. **a, c, e**. The correct procedure for using a meter-dosed inhaler is: Shake the inhaler well and remove the mouthpiece cover; breathe normally through the spacer; depress the canister releasing one puff into the spacer and inhale slowly and deeply; after inhaling, hold breath for 5 to 10 seconds, or as long as possible, and then exhale slowly through pursed lips; wait 1 to 5 minutes as prescribed before administering the next puff; and gargle and rinse with tap water after using the MDI.

. **c.** The nurse should first assess the patient's concern about the medication and provide education, if needed. If an allergy is the cause, the nurse should withhold the medication and notify the health care provider. Encouraging or manipulating a patient to take a pill undermines the patient's trust, especially if an adverse reaction occurs.

. **a.** Medication reconciliation has been shown to decrease the incidence of medication errors that occur at points of transition in patient care. This process maintains a current, accurate list of medications a patient has received. Morning care can be delayed, if not yet given. Obtaining the patient's meal can be delegated to another person on the unit (e.g., AP). A report must be taken prior to accepting the patient for transfer.

. **a.** Hang the piggyback container on the IV pole, positioning it higher than the primary IV bag. When infusing by gravity, the primary IV fluid container must be lowered. Closing the roller clamp to the secondary line will impede flow of the piggybacked medication.

. **a.** Enoxaparin should be administered in the alternating "left and right anterolateral and left and right posterolateral abdominal wall[s]." Air, inserted by the manufacturer, should not be expelled prior to use. As this is a low–molecular-weight heparin, do not massage the area to prevent bruising. Recapping any syringe places the nurse at risk for needlestick injury and is not recommended.

. **c.** Older adults may have difficulty swallowing medications and may find it easier to take their medications when crushed or given in liquid form. Combine the crushed medication with a small amount of soft food, such as applesauce or pudding; 120 mL or a bowl of pudding is a large amount; should the patient not finish all the food, an accurate assessment of medication taken cannot be assessed. Only medications designated as chewable can be used in this way.

. **b.** Drugs with extensive or variable first-pass effects, such as nitroglycerin, are not given orally because most of the drug would be destroyed by the liver, with little or no drug left to work in the body. Sublingual medications should not be swallowed, but rather held in place so that complete absorption can occur. Before administering a sublingual or buccal drug, offer the patient water (if permitted) or oral care (if NPO). Placing a tablet between the cheek and gum is consistent with the buccal route of administration, not sublingual. Enteric-coated tablets are designed to dissolve after passing through the stomach.

. **c.** Drug doses for children are calculated by weight in kilograms or BSA. The weight is needed for the provider to write the prescription.

. **c.** For children ages 3 years and younger, the nurse teaches the parent or caregiver to pull the pinna down and back to straighten the auditory canal, then instill the medication. For adults, the pinna is pulled up and back; for school-age children, the pinna is pulled straight back. The nurse does not insert cotton swabs in the ear; rather, the nurse can wipe the external ear of drainage, if necessary.

. **b.** The nurse is responsible for safe medication administration, including interpreting therapeutic serum drug levels. The nurse withholds the medication based on the toxic (high) drug level. Next, the nurse collaborates with the health care provider to determine if a dose adjustment is indicated. Prescribing is outside the nurse's scope of practice; determining a half dose is needed is a prescription. The patient's renal function will be evaluated periodically, but it is most important not to give a medication when the blood level demonstrates toxicity.

. **a.** Lowered protein levels in the body means less drug bound to plasma proteins, which leads to a higher concentration of free (unbound) drug in the body. This higher drug concentration increases the risk for adverse effects.

. **b.** Medications that are identified as teratogenic have the potential to cause developmental defects in the embryo or fetus and are contraindicated. The nurse must hold the medication and notify the health care provider of the pregnant person's pregnancy status. The patient is not the best person to determine the impact of this medication on the fetus; the medication is a teratogen, even with dose reduction.

. **d.** When administering PRN medication, the patient receives medication when it is requested or required, and when the clinical parameters of the order, including timing between doses, are met. PRN orders are commonly written for the treatment of symptoms, in this instance, pain.

MEDICATION CALCULATION PROBLEMS

. Metoprolol 25 mg PO is prescribed. Metoprolol is available as 50-mg tablets. How many tablets would the nurse administer?

. Phenytoin 100 mg PO is prescribed to be given through a nasogastric tube. Phenytoin is available as 30 mg/5 mL. How much would the nurse administer?

. Captopril 12.5 mg PO is prescribed. Captopril is available as 25-mg tablets. How many tablets would the nurse administer?

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

. Potassium chloride, 20 mEq, is prescribed. Potassium chloride is available as 10 mEq per tablet. How many tablets would the nurse administer?

. Digoxin 0.0625 mg PO is prescribed. Digoxin is available as 0.125-mg tablets. How many tablets would the nurse administer?

. Propantheline bromide 15 mg is prescribed. Propantheline bromide is available as 7.5-mg tablets. How many tablets would the nurse administer?

. Ciprofloxacin 500 mg PO is prescribed. Ciprofloxacin is available as 250-mg tablets. How many tablets would the nurse administer?

. Heparin bolus of 65 units/kg IV × 1 now is prescribed. The patient weighs 220 lb. Heparin is available in 10,000 units/mL vials. How many mL would the nurse administer?

. Theophylline elixir 100 mg PO is prescribed by way of a percutaneous endoscopic gastrostomy tube. Theophylline elixir is available as 80 mg/15 mL. How much would the nurse administer?

. Clonidine 0.1 mg PO is prescribed. Clonidine is available as 0.2-mg tablets. How many tablets would the nurse administer?

. Vitamin K 10 mg given IM is prescribed. Vitamin K is available as 5 mg/mL. How much would the nurse administer?

. Morphine sulfate 10 mg IV is prescribed. Morphine is available as 4 mg/mL. How much would the nurse administer?

. Midazolam 3 mg IM is prescribed. Midazolam is available as 5 mg/mL. How much would the nurse administer?

. Ondansetron 0.15 mg/kg is prescribed. Ondansetron is available as 2 mg/mL. The patient weighs 30 kg. How much would the nurse administer?

. Epoetin alfa 2,000 units SC is prescribed. Epoetin alfa is available in 4,000 units/mL. How much would the nurse administer?

. Methylprednisolone 40 mg IV is prescribed every 8 hours. Methylprednisolone is available 125 mg/2 mL. How many mL would the nurse administer?

. Octreotide acetate 50 mcg SC is prescribed. Octreotide is available as 100 mcg/mL. How much would the nurse administer?

. Lisinopril 40 mg once a day is prescribed. Lisinopril is available as an oral solution 8 mg/mL. How much should the nurse administer via the enteral feeding tube?

. Prochlorperazine 7.5 mg IM is prescribed. Prochlorperazine is available as 5 mg/mL. How much would the nurse administer?

. Glycopyrrolate 0.4 mg IM is prescribed. Glycopyrrolate is available as 200 mcg/mL. How much would the nurse administer?

. Gentamycin 80 mg in 100 mL IV is prescribed. The administration set delivers 10 gtt/mL. If the medication runs over 30 minutes, how many drops per minute (gtt/min) should the nurse administer?

. The IV fluid 0.9% Sodium Chloride is prescribed to run continuously at 75 mL/hr. The administration set delivers 10 gtt/mL. How many drops per minute (gtt/min) should the nurse administer?

ANSWERS TO MEDICATION CALCULATION PROBLEMS

FORMULA METHOD ("Desire over have")	FORMULA METHOD (Proportions)	DIMENSIONAL ANALYSIS (Chemistry)
$\frac{\text{dose desired}}{\text{(quantity desired)}} \times \text{quantity on hand} = \text{desired quantity}$ ***Need to make sure to multiply by the quantity on hand, even if that quantity is one (1)*	$\frac{\text{dose on hand}}{\text{quantity on hand}} = \frac{\text{dose desired}}{x\ \text{(quantity desired)}}$ ***Need to make sure that dosages are in both numerators and quantities are in the denominators*	What you are solving for = dose desired × dose available ***This formula may also include conversions as needed. The goal is to rely on the mathematical principles associated with multiplying fractions.*
LEAST PREFERABLE…BUT ALIGNS WITH MENTAL MATH	PREFERRED FOR SIMPLE CALCULATIONS	RECOMMENDED FOR SIMPLE AND COMPLEX CALCULATIONS OR WHERE CONVERSIONS ARE REQUIRED
NUMBER 1		
$\frac{25\ \text{mg}}{50\ \text{mg}} \times 1\ \text{tablet} = x$ $\frac{25\ \cancel{\text{mg}}}{50\ \cancel{\text{mg}}} \times 1\ \text{tablet} = 0.5 \text{ or } \frac{1}{2}\ \text{tablet}$	$\frac{50\ \text{mg}}{1\ \text{tablet}} = \frac{25\ \text{mg}}{x\ \text{tablet}}$ $50x = 25$ $\frac{50x}{50} = \frac{25}{50}$ $x = 0.5 \text{ or } \frac{1}{2}\ \text{tablet}$	$\text{tablet} = \frac{1\ \text{tablet}}{50\ \text{mg}} \times \frac{25\ \text{mg}}{1}$ $\text{tablet} = \frac{1\ \text{tablet}}{\overset{2}{\cancel{50}}\ \cancel{\text{mg}}} \times \frac{\overset{1}{\cancel{25}}\ \cancel{\text{mg}}}{1} = 0.5 \text{ or } \frac{1}{2}\ \text{tablet}$
NUMBER 2		
$\frac{100\ \text{mg}}{30\ \text{mg}} \times 5\ \text{mL} = x$ $\frac{100\ \cancel{\text{mg}}}{30\ \cancel{\text{mg}}} \times 5\ \text{mL} = 16.6\overline{6} = 16.7\ \text{mL}$	$\frac{30\ \text{mg}}{5\ \text{mL}} = \frac{100\ \text{mg}}{x\ \text{mL}}$ $30x = 500$ $\frac{30x}{30} = \frac{500}{30}$ $x = 16.6\overline{6} = 16.7\ \text{mL}$	$\text{mL} = \frac{5\ \text{mL}}{30\ \text{mg}} \times \frac{100\ \text{mg}}{1}$ $\text{mL} = \frac{5\ \text{mL}}{30\ \cancel{\text{mg}}} \times \frac{100\ \cancel{\text{mg}}}{1} = 16.6\overline{6} = 16.7\ \text{mL}$

NUMBER 8

Step one – Convert:

220 lb ÷ 2.2 lb/kg

220 ~~lb~~ ÷ 2.2 ~~lb~~/kg = 100 kg

Step two – Determine Dose:

65 units/~~kg~~ × 100 ~~kg~~ = 6,500 units

Step three – Calculate:

$$\frac{6{,}500 \text{ units}}{10{,}000 \text{ units}} \times 1 \text{ mL} = x$$

$$\frac{6{,}500 \text{ } \cancel{\text{units}}}{10{,}000 \text{ } \cancel{\text{units}}} \times 1 \text{ mL} = 0.65 \text{ mL}$$

Step one – Convert:

$$\frac{2.2 \text{ lb}}{1 \text{ kg}} = \frac{220 \text{ lb}}{x \text{ (kg)}}$$

$$2.2x = 220$$

$$\frac{2.2x}{2.2} = \frac{220}{2.2}$$

$$x = 100 \text{ kg}$$

Step two – Determine Dose:

$$\frac{1 \text{ kg}}{65 \text{ units}} = \frac{100 \text{ kg}}{x \text{ units}}$$

$$x = 6{,}500 \text{ units}$$

Step three – Calculate:

$$\frac{10{,}000 \text{ units}}{1 \text{ mL}} = \frac{6{,}500 \text{ units}}{x \text{ (mL)}}$$

$$10{,}000x = 6{,}500 \text{ units}$$

$$\frac{10{,}000x}{10{,}000} = \frac{6{,}500}{1}$$

$$x = 0.65 \text{ mL}$$

$$\text{mL} = \frac{1 \text{ mL}}{10{,}000 \text{ units}} \times \frac{65 \text{ units/kg}}{1} \times \frac{220 \text{ lb}}{1} \times \frac{1 \text{ kg}}{2.2 \text{ lb}}$$

$$\text{mL} = \frac{1 \text{ mL}}{10{,}000 \text{ } \cancel{\text{units}}} \times \frac{65 \text{ } \cancel{\text{units}}/\cancel{\text{kg}}}{1} \times \frac{220 \text{ } \cancel{\text{lb}}}{1} \times \frac{1 \text{ } \cancel{\text{kg}}}{2.2 \text{ } \cancel{\text{lb}}}$$

$$= \frac{6{,}500}{10{,}000} = 0.65 \text{ mL}$$

**Follow the standard rounding rules: For numbers >1, round to the 10th (tenth); for numbers <1, round to the 100th (hundredth).

NUMBER 9

$$\frac{100 \text{ mg}}{80 \text{ mg}} \times 15 \text{ mL} = x$$

$$\frac{100 \text{ } \cancel{\text{mg}}}{80 \text{ } \cancel{\text{mg}}} \times 15 = 18.75 = 18.8 \text{ mL}$$

$$\frac{80 \text{ mg}}{15 \text{ mL}} = \frac{100 \text{ mg}}{x \text{ (mL)}}$$

$$80x = 1{,}500$$

$$\frac{80x}{80} = \frac{1{,}500}{80}$$

$$x = 18.7 = 18.8 \text{ mL}$$

$$\text{mL} = \frac{15 \text{ mL}}{80 \text{ mg}} \times \frac{100 \text{ mg}}{1}$$

$$\text{mL} = \frac{15 \text{ mL}}{80 \text{ } \cancel{\text{mg}}} \times \frac{100 \text{ } \cancel{\text{mg}}}{1} = 18.75 = 18.8 \text{ mL}$$

**Follow the standard rounding rules: For numbers >1, round to the 10th (tenth); for numbers <1, round to the 100th (hundredth).

NUMBER 10

$$\frac{0.1\text{ mg}}{0.2\text{ mg}} \times 1\text{ tablet} = x$$

$$\frac{0.1\ \cancel{\text{mg}}}{0.2\ \cancel{\text{mg}}} \times 1\text{ tablet} = 0.5 \text{ or } \tfrac{1}{2} \text{ tablet}$$

$$\frac{0.2\text{ mg}}{1\text{ tablet}} = \frac{0.1\text{ mg}}{x\text{ tablet}}$$

$$0.2x = 0.1$$

$$\frac{0.2x}{0.2} = \frac{0.1}{0.2}$$

$$x = 0.5 \text{ or } \tfrac{1}{2} \text{ tablet}$$

$$\text{tablet} = \frac{1\text{ tablet}}{0.2\text{ mg}} \times \frac{0.1\text{ mg}}{1}$$

$$\text{tablet} = \frac{1\text{ tablet}}{0.2\ \cancel{\text{mg}}} \times \frac{0.1\ \cancel{\text{mg}}}{1} = 0.5 \text{ or } \tfrac{1}{2} \text{ tablet}$$

NUMBER 11

$$\frac{10\text{ mg}}{5\text{ mg}} \times 1\text{ mL} = x$$

$$\frac{10\ \cancel{\text{mg}}}{5\ \cancel{\text{mg}}} \times 1\text{ mL} = 2\text{ mL}$$

$$\frac{5\text{ mg}}{1\text{ mL}} = \frac{10\text{ mg}}{x\text{ mL}}$$

$$5x = 10$$

$$\frac{5x}{5} = \frac{10}{5}$$

$$x = 2\text{ mL}$$

$$\text{mL} = \frac{1\text{ mL}}{5\text{ mg}} \times \frac{10\text{ mg}}{1}$$

$$\text{mL} = \frac{1\text{ mL}}{\overset{1}{\cancel{5}}\ \cancel{\text{mg}}} \times \frac{\overset{2}{10}\ \cancel{\text{mg}}}{1} = 2\text{ mL}$$

NUMBER 12

$$\frac{10\text{ mg}}{4\text{ mg}} \times 1\text{ mL} = x$$

$$\frac{10\ \cancel{\text{mg}}}{4\ \cancel{\text{mg}}} \times 1\text{ mL} = 2.5\text{ mL}$$

$$\frac{4\text{ mg}}{1\text{ mL}} = \frac{10\text{ mg}}{x\text{ mL}}$$

$$4x = 10$$

$$\frac{4x}{4} = \frac{10}{4}$$

$$x = 2.5\text{ mL}$$

$$\text{mL} = \frac{1\text{ mL}}{4\text{ mg}} \times \frac{10\text{ mg}}{1}$$

$$\text{mL} = \frac{1\text{ mL}}{4\ \cancel{\text{mg}}} \times \frac{10\ \cancel{\text{mg}}}{1} = 2.5\text{ mL}$$

**Follow the standard rounding rules: For numbers >1, round to the 10th (tenth); for numbers <1, round to the 100th (hundredth).

NUMBER 13

$$\frac{3\text{ mg}}{5\text{ mg}} \times 1\text{ mL} = x$$

$$\frac{3\ \cancel{\text{mg}}}{5\ \cancel{\text{mg}}} \times 1\text{ mL} = 0.6\text{ mL}$$

$$\frac{5\text{ mg}}{1\text{ mL}} = \frac{3\text{ mg}}{x\text{ mL}}$$

$$5x = 3$$

$$\frac{5x}{5} = \frac{3}{5}$$

$$x = 0.6\text{ mL}$$

$$\text{mL} = \frac{1\text{ mL}}{5\text{ mg}} \times \frac{3\text{ mg}}{1}$$

$$\text{mL} = \frac{1\text{ mL}}{5\ \cancel{\text{mg}}} \times \frac{3\ \cancel{\text{mg}}}{1} = 0.6\text{ mL}$$

email 960126734@qq.com

NUMBER 14

Step one – Determine Dose:

$0.15\ \text{mg/}\cancel{\text{kg}} \times 30\cancel{\text{kg}} = 4.5\ \text{mg}$

Step two – Calculate:

$$\frac{4.5\ \text{mg}}{2\ \text{mg}} \times 1\ \text{mL} = x$$

$$\frac{4.5\ \cancel{\text{mg}}}{2\ \cancel{\text{mg}}} \times 1\ \text{mL} = 2.25 = 2.3\ \text{mL}$$

Step one – Determine Dose:

$$\frac{1\ \text{kg}}{0.15\ \text{mg}} = \frac{30\ \text{kg}}{x\ \text{mg}}$$

$$x = 4.5\ \text{mg}$$

Step two – Calculate:

$$\frac{2\ \text{mg}}{1\ \text{mL}} = \frac{4.5\ \text{mg}}{x\ (\text{mL})}$$

$$2x = 4.5$$

$$\frac{2x}{2} = \frac{4.5}{2}$$

$$x = 2.25 = 2.3\ \text{mL}$$

$$\text{mL} = \frac{1\ \text{mL}}{2\ \text{mg}} \times \frac{0.15\ \text{mg/kg}}{1} \times \frac{30\ \text{kg}}{1}$$

$$\text{mL} = \frac{1\ \text{mL}}{2\ \cancel{\text{mg}}} \times \frac{0.15\ \cancel{\text{mg}}/\cancel{\text{kg}}}{1} \times \frac{30\ \cancel{\text{kg}}}{1} = 2.25 = 2.3\ \text{mL}$$

**Follow the standard rounding rules: For numbers >1, round to the 10th (tenth); for numbers <1, round to the 100th (hundredth).

NUMBER 15

$$\frac{2{,}000\ \text{units}}{4{,}000\ \text{units}} \times 1\ \text{mL} = x$$

$$\frac{2{,}000\ \cancel{\text{units}}}{4{,}000\ \cancel{\text{units}}} \times 1\ \text{mL} = 0.5 \text{ or } \tfrac{1}{2}\ \text{mL}$$

$$\frac{4{,}000\ \text{units}}{1\ \text{mL}} = \frac{2{,}000\ \text{units}}{x\ (\text{mL})}$$

$$4{,}000x = 2{,}000$$

$$\frac{4{,}000x}{4{,}000} = \frac{2{,}000}{4{,}000}$$

$$x = 0.5 \text{ or } \tfrac{1}{2}\ \text{mL}$$

$$\text{mL} = \frac{1\ \text{mL}}{4{,}000\ \text{units}} \times \frac{2{,}000\ \text{units}}{1}$$

$$\text{mL} = \frac{1\ \text{mL}}{\frac{4{,}000}{2}\ \cancel{\text{units}}} \times \frac{\overset{1}{\cancel{2{,}000}\ \cancel{\text{units}}}}{1} = 0.5 \text{ or } \tfrac{1}{2}\ \text{mL}$$

NUMBER 16

$$\frac{40\ \text{mg}}{125\ \text{mg}} \times 2\ \text{mL} = x$$

$$\frac{40\ \cancel{\text{mg}}}{125\ \cancel{\text{mg}}} \times 2\ \text{mL} = 0.64\ \text{mL}$$

$$\frac{125\ \text{mg}}{2\ \text{mL}} = \frac{40\ \text{mg}}{x\ (\text{mL})}$$

$$125x = 80$$

$$\frac{125x}{125} = \frac{80}{125}$$

$$x = 0.64\ \text{mL}$$

$$\text{mL} = \frac{2\ \text{mL}}{125\ \text{mg}} \times \frac{40\ \text{mg}}{1}$$

$$\text{mL} = \frac{2\ \text{mL}}{125\ \cancel{\text{mg}}} \times \frac{40\ \cancel{\text{mg}}}{1} = 0.64\ \text{mL}$$

**Follow the standard rounding rules: For numbers >1, round to the 10th (tenth); for numbers <1, round to the 100th (hundredth).

**For numbers >1, round to the 10th (tenth); for numbers <1, round to the 100th (hundredth).

NUMBER 17

$$\frac{50 \text{ mcg}}{100 \text{ mcg}} \times 1 \text{ mL} = x$$

$$\frac{50 \cancel{\text{ mcg}}}{100 \cancel{\text{ mcg}}} \times 1 \text{ mL} = 0.5 \text{ or } \tfrac{1}{2} \text{ mL}$$

$$\frac{100 \text{ mcg}}{1 \text{ mL}} = \frac{50 \text{ mcg}}{x \text{ (mL)}}$$

$$100x = 50$$

$$\frac{100x}{100} = \frac{50}{100}$$

$$x = 0.5 \text{ or } \tfrac{1}{2} \text{ mL}$$

$$\text{mL} = \frac{1 \text{ mL}}{100 \text{ mcg}} \times \frac{50 \text{ mcg}}{1}$$

$$\text{mL} = \frac{1 \text{ mL}}{\overset{2}{\cancel{100}} \text{ mcg}} \times \frac{\overset{1}{\cancel{50}} \cancel{\text{ mcg}}}{1} = 0.5 \text{ or } \tfrac{1}{2} \text{ mL}$$

NUMBER 18

$$\frac{40 \text{ mg}}{8 \text{ mg}} \times 1 \text{ mL} = x$$

$$\frac{40 \cancel{\text{ mg}}}{8 \cancel{\text{ mg}}} \times 1 \text{ mL} = 5 \text{ mL}$$

$$\frac{8 \text{ mg}}{1 \text{ mL}} = \frac{40 \text{ mg}}{x \text{ (mL)}}$$

$$8x = 40$$

$$\frac{8x}{8} = \frac{40}{8}$$

$$x = 5 \text{ mL}$$

$$\text{mL} = \frac{1 \text{ mL}}{8 \text{ mg}} \times \frac{40 \text{ mg}}{1}$$

$$\text{mL} = \frac{1 \text{ mL}}{\overset{1}{\cancel{8}} \cancel{\text{ mg}}} \times \frac{\overset{5}{\cancel{40}} \cancel{\text{ mg}}}{1} = 5 \text{ mL}$$

NUMBER 19

$$\frac{7.5 \text{ mg}}{5 \text{ mg}} \times 1 \text{ mL} = x$$

$$\frac{7.5 \cancel{\text{ mg}}}{5 \cancel{\text{ mg}}} \times 1 \text{ mL} = 1.5 \text{ mL}$$

$$\frac{5 \text{ mg}}{1 \text{ mL}} = \frac{7.5 \text{ mg}}{x \text{ (mL)}}$$

$$5x = 7.5$$

$$\frac{5x}{5} = \frac{7.5}{5}$$

$$x = 1.5 \text{ mL}$$

$$\text{mL} = \frac{1 \text{ mL}}{5 \text{ mg}} \times \frac{7.5 \text{ mg}}{1}$$

$$\text{mL} = \frac{1 \text{ mL}}{5 \cancel{\text{ mg}}} \times \frac{7.5 \cancel{\text{ mg}}}{1} = 1.5 \text{ mL}$$

NUMBER 20

Step one – Convert:

200 mcg = 200 mcg (÷1,000) = 0.2 mg

Step two – Calculate:

$$\frac{0.4\text{ mg}}{0.2\text{ mg}} \times 1\text{ mL} = x \qquad \frac{0.4\ \cancel{\text{mg}}}{0.2\ \cancel{\text{mg}}} \times 1\text{ mL} = 2\text{ mL}$$

Step one – Convert:

$$\frac{1{,}000\text{ mcg}}{1\text{ mg}} = \frac{200\text{ mcg}}{x\,(\text{mg})}$$

$$1{,}000x = 200$$

$$\frac{1{,}000x}{1{,}000} = \frac{200}{1{,}000}$$

$$x = 0.2\text{ mg}$$

Step two – Calculate:

$$\frac{0.2\text{ mg}}{1\text{ mL}} = \frac{0.4\text{ mg}}{x\,(\text{mL})}$$

$$0.2x = 0.4$$

$$\frac{0.2x}{0.2} = \frac{0.4}{0.2}$$

$$x = 2\text{ mL}$$

$$\text{mL} = \frac{1\text{ mL}}{200\text{ mcg}} \times \frac{0.4\text{ mg}}{1} \times \frac{1{,}000\text{ mcg}}{1\text{ mg}}$$

$$\text{mL} = \frac{1\text{ mL}}{200\ \cancel{\text{mcg}}} \times \frac{0.4\ \cancel{\text{mg}}}{1} \times \frac{1{,}000\ \cancel{\text{mcg}}}{1\ \cancel{\text{mg}}} = 2\text{ mL}$$

OR

OR

Step one – Convert:

0.4 mg = 0.400 (×1,000) = 400 mcg

Step two – Calculate:

$$\frac{400\text{ mcg}}{200\text{ mcg}} \times 1\text{ mL} = x$$

$$\frac{400\ \cancel{\text{mcg}}}{200\ \cancel{\text{mcg}}} \times 1\text{ mL} = 2\text{ mL}$$

Step one – Convert:

$$\frac{1\text{ mg}}{1{,}000\text{ mcg}} = \frac{0.4\text{ mg}}{x\text{ mcg}}$$

$$x = 400\text{ mcg}$$

Step two – Calculate:

$$\frac{200\text{ mcg}}{1\text{ mL}} = \frac{400\text{ mcg}}{x\,(\text{mL})}$$

$$200x = 400$$

$$\frac{200x}{200} = \frac{400}{200}$$

$$x = 2\text{ mL}$$

Number 21		
Drop Factor (gtt/mL) × Volume to be Infused (mL)	$\frac{10\ \text{gtt}/\cancel{\text{mL}} \times 100\ \cancel{\text{mL}}}{30\ \text{minutes}} = 33.33333 = 33\ \text{gtt/min}$	Time in Minutes (min)
**Keep in mind that we are counting actual drops in the drip chamber, so gtt/min must be rounded to the whole number—we cannot visualize a third of a drop!		
Number 22		
Drop Factor (gtt/mL) × Volume to be Infused (mL)	$\frac{10\ \text{gtt}/\cancel{\text{mL}} \times 75\ \cancel{\text{mL}}}{60\ \text{minutes}} = 12.5 = 13\ \text{gtt/min}$	Time in Minutes (min)
**Keep in mind that you must provide minutes…not hours. There are 60 minutes in an hour, so use 60 in the formula.

Perioperative Nursing

Molly Greenbaum

Molly, a 38-year-old female who is scheduled for a vaginal hysterectomy later in the day, arrives at the hospital at 0630. With tears in her eyes and wringing her hands, she states, “I really didn’t sleep very much last night. I kept thinking about the surgery.”

Marcus Benjamin

Marcus, a 73-year-old male, has just had a total hip replacement under general anesthesia and is transferred to the postanesthesia care unit (PACU). His vital signs are stable. He has an intravenous catheter in his right antecubital space, infusing at 125 mL/hr, and an indwelling urinary catheter in place, draining clear yellow urine. The dressing over the surgical site is clean and dry, without any drainage.

Gabrielle McAllister

Gabrielle McAllister is a 5-year-old female scheduled for a tonsillectomy and adenoidectomy at a hospital-based, same-day surgery unit. She was born with a congenital cardiac defect and has had six prior surgeries. She is small for her age and is allergic to latex but is an otherwise healthy kindergarten student.

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Describe the surgical experience, including perioperative phases, classifications of surgery, types of anesthesia, informed consent and advance directives, and outpatient/same-day surgery.
. Conduct a preoperative nursing history and physical assessment to identify patient strengths as well as factors that increase risks for surgical and postoperative complications.
. Prepare a patient physically and psychologically for surgery.
. Identify assessments and interventions specific to the prevention of complications in the immediate and early postoperative phases.
. Use the nursing process to develop an individualized plan of care for the surgical patient during each phase of the perioperative period.

Nursing Concepts

Management of care
Evidence-based practice
Teaching and learning/patient education
Thermoregulation

Key Terms

anesthesia
atelectasis
deep vein thrombosis (DVT)
elective surgery
emergency surgery
general anesthesia
hemorrhage
Hemorrhage
hypothermia
local anesthesia
moderate sedation/analgesia
perioperative nursing
perioperative phases
pneumonia
postanesthesia care unit (PACU)
pulmonary embolism
regional anesthesia
shock
thrombophlebitis
time-out
topical anesthesia
urgent surgery
venous thromboembolism (VTE)

The treatment of many illnesses and injuries includes some type of operative or other invasive procedure. In this chapter, we will refer to the myriad operative and other invasive procedures (Association of periOperative Registered Nurses [AORN], 2020) performed in the operating room or surgical suite, using the general term *surgery*. Surgery requires collaboration and the integration of role-specific knowledge and skills of multiple care providers to ensure patient safety

and promote good outcomes. Surgery may be done for a variety of reasons: to cure or minimize disease; to diagnose the specific presence of a disease or condition; to reconstruct or eliminate a defect; to enhance form and function; to palliate, or offer comfort, when cure is not possible; to follow up or monitor an incurable disease process; or to offer a preventive option when disease is inevitable, such as an elective, prophylactic mastectomy for a person at high risk for breast cancer. Surgery may be planned or unplanned, elective/optional or necessary, major or minor, and may involve any body part or system. Surgery is a stressor that requires physical and psychosocial adaptations for both the patient and the family. The patient's recovery from a surgical procedure requires skillful and knowledgeable nursing care, whether the surgery is done on an outpatient basis or in the hospital. See the accompanying Reflective Practice box (on pages 1038–1039) for an example of nursing care for a patient who has undergone surgery.

Nursing care provided for the patient before, during, and after surgery is called **perioperative nursing**. All members of the interprofessional team use the term *perioperative* to describe the entire time surrounding an operative or other invasive procedure. The nursing process is used to guide assessments and interventions that promote the recovery of health, prevent further injury or illness, and facilitate coping with alterations in physical structure and function.

A conceptual model for perioperative nursing care is shown in Figure 31-1 (on page 1039). In this model, the patient is at the center of all care activities. Surrounding the patient are four domains. Three of these domains—safety, physiologic responses, and behavioral responses—are integral to patient care. The fourth domain, health system, represents the structural elements and other health system activities that must be present to support safe, effective, high-quality patient care (AORN, 2011).

With this model, each domain has desired outcomes. These outcomes are identified first in the model because perioperative nursing is preventive and outcome-focused in nature. This is in contrast to the usual progression of the nursing process, which begins with assessment. Thus, perioperative nurses base their plans of care on recognized desired outcomes. Perioperative nurses assess the patient for the relevance of the outcome, then identify actual or potential nursing problems and plan interventions. The Perioperative Nursing Data Set (PNDS) reflects AORN-designed, standardized nursing language that captures the perioperative patient experience from preadmission to discharge (AORN, 2020).

Technology Alert

Established in 2017, AORN Syntegrity® seamlessly integrates the language from the Perioperative Nursing Data Set (PNDS) and AORN's evidence-based Guidelines for Perioperative Practice with the Electronic Health Record (EHR) to help streamline the communication, scheduling, workflow, analytics, and documentation processes inherent in the perioperative phases (AORN, 2020).

One of the most significant roles of the perioperative nurse is that of collaborator—the nurse interfaces directly and indirectly with other nurses, surgeons, support personnel, anesthesia professionals, perioperative services executives, quality improvement personnel, and risk management experts. Evidence-based practice that considers patient and family preferences, clinical expertise of the health care provider, and the best evidence available informs decision making at all stages of the complex perioperative process. The ultimate, shared goal is to provide safe, quality care for the vulnerable perioperative patient (AORN, 2020).

The type of surgery scheduled influences the desired outcomes, health problem identification, assessments, and interventions carried out by the nurse. The perioperative nurse's goal is to promote and assist the patient and family to achieve a level of wellness equal to or greater than what they had prior to the surgical procedure (AORN, 2020).

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO ETHICAL AND LEGAL SKILLS

During a recent clinical experience on a level II ICU, I cared for Ron Johnson, a middle-aged male patient who had an extensive medical history that included gunshot wounds, bilateral leg amputations, paraplegia, and several surgeries. Because of this, he had lengthy hospital stays and was known by the staff as being a difficult and manipulative patient. During my encounter with him, he had just returned from the OR where they had performed a urinary diversion. He was ordered to be nothing by mouth (NPO) for 24 hours following surgery. However, he claimed that his surgeon had told him that he would be able to eat immediately after the surgery, and he was demanding that I give him food and fluids. "I want some food and I want it now!" I told the patient that I had to follow the orders in his chart and that it was unlikely that he would be able to have anything by mouth during my shift. He asked me to explain the reasons for being NPO after surgery, and I did my best under the time constraints by telling him that the bowel is affected by anesthesia, and it is not ready to handle the intake of food and fluids. In all honesty, I didn't know the major consequences of eating or drinking after surgery; however, I didn't admit this to him. He was obviously not satisfied with my explanation because when I returned from my lunch break, he was sitting in front of a

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

lunch tray. He had talked a new nursing assistant into getting him the items. He made the decision to act against my instructions and the instructions of his surgeon, perhaps because I was not able to give him a clear, articulate explanation of his NPO status.

Thinking Outside the Box: Possible Courses of Action

- Tell the patient that I was unable to give him the best explanation of his NPO status, informing him that I would return in 5 to 10 minutes after consulting with a nurse, and deciding the best way to articulate to him the consequences of ignoring the order.
- Avoid giving him any explanation at all, assuming that because of his extensive surgical history, he knew the reasons why he must not eat or drink.
- Ask a nurse or the dietitian to explain the NPO order.
- Alert the surgeon that this patient was at risk for being nonadherent and ask her to come to see the patient as soon as possible.

Evaluating a Good Outcome: How Do I Define Success?

- The patient verbalizes an understanding of my explanation and the consequences of his actions.
- The patient complies with the health care provider's orders and with my instructions.
- The patient remains free of injuries/complications.
- I feel competent in my explanations and actions.
- I take responsibility for the impact of my (in)action with the patient and partner with him in decision making.

Personal Learning: Here's to the Future!

This patient taught me a great deal. He taught me that sometimes, rather than giving an inadequate explanation, it would be better to admit that you do not know or that your knowledge is not up to par in a particular area. I should have been honest with Mr. Johnson, admitting that I was unsure about why he wasn't allowed to eat or drink. It would have been more advantageous to consult with someone else before giving him a more thorough explanation. I also should have recognized that Mr. Johnson was exhibiting extreme frustration and depression, placing him at high risk for nonadherence. All he needed was someone to take extra time with him, offering compassion and support. Unfortunately, the patient did not comply with the order and thus was at risk for developing serious complications, such as a bowel obstruction. I alerted the surgeon of the patient's actions and, luckily, the surgeon was understanding. In the future, I will make a major effort to gather the appropriate information to give patients a thorough, understandable explanation when they ask for specific information.

Colleen Kilcullen, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How would you respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? Can you think of other ways to approach this situation? What *knowledge, skills,* and *attitudes* do you need to develop in order to continuously improve quality and safety when caring for patients like Mr. Johnson?

Patient-Centered Care: What information about his postoperative instructions needs to be clearly communicated to Mr. Johnson? How might his past history have influenced the nursing student's actions? Explain. If you were this nursing student, would Mr. Johnson's past history have influenced you? Why or why not? How could you involve Mr. Johnson as a partner in coordinating his care, thus minimizing his frustration? How could you provide emotional support?

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to provide clear, comprehensive information to Mr. Johnson? Would collaboration with your instructor or Mr. Johnson's nurse have resulted in another approach to communicating and explaining the health care provider's orders in a timely manner?

Safety/Evidence-Based Practice: Can you obtain any resources/articles from the nursing literature that provide information and guidance regarding risks associated with intake of food and fluids in the immediate postoperative period? Do you think your response to Mr. Johnson provided a safe environment for him?

Informatics: What information should be electronically documented regarding your interaction with Mr.

Johnson? Is there a better way to describe this patient or is *noncompliant* appropriate? What about the word *nonadherence*? Do those words have different connotations? Can you identify the essential information that must be noted in his electronic record to support safe patient care?

THE SURGICAL EXPERIENCE

Regardless of the surgical or interventional procedure required or the setting in which it is performed, all patients progress through specific phases, all patients must provide informed consent for the surgery or procedure, and some surgeries and procedures require some type of anesthesia and monitoring support.

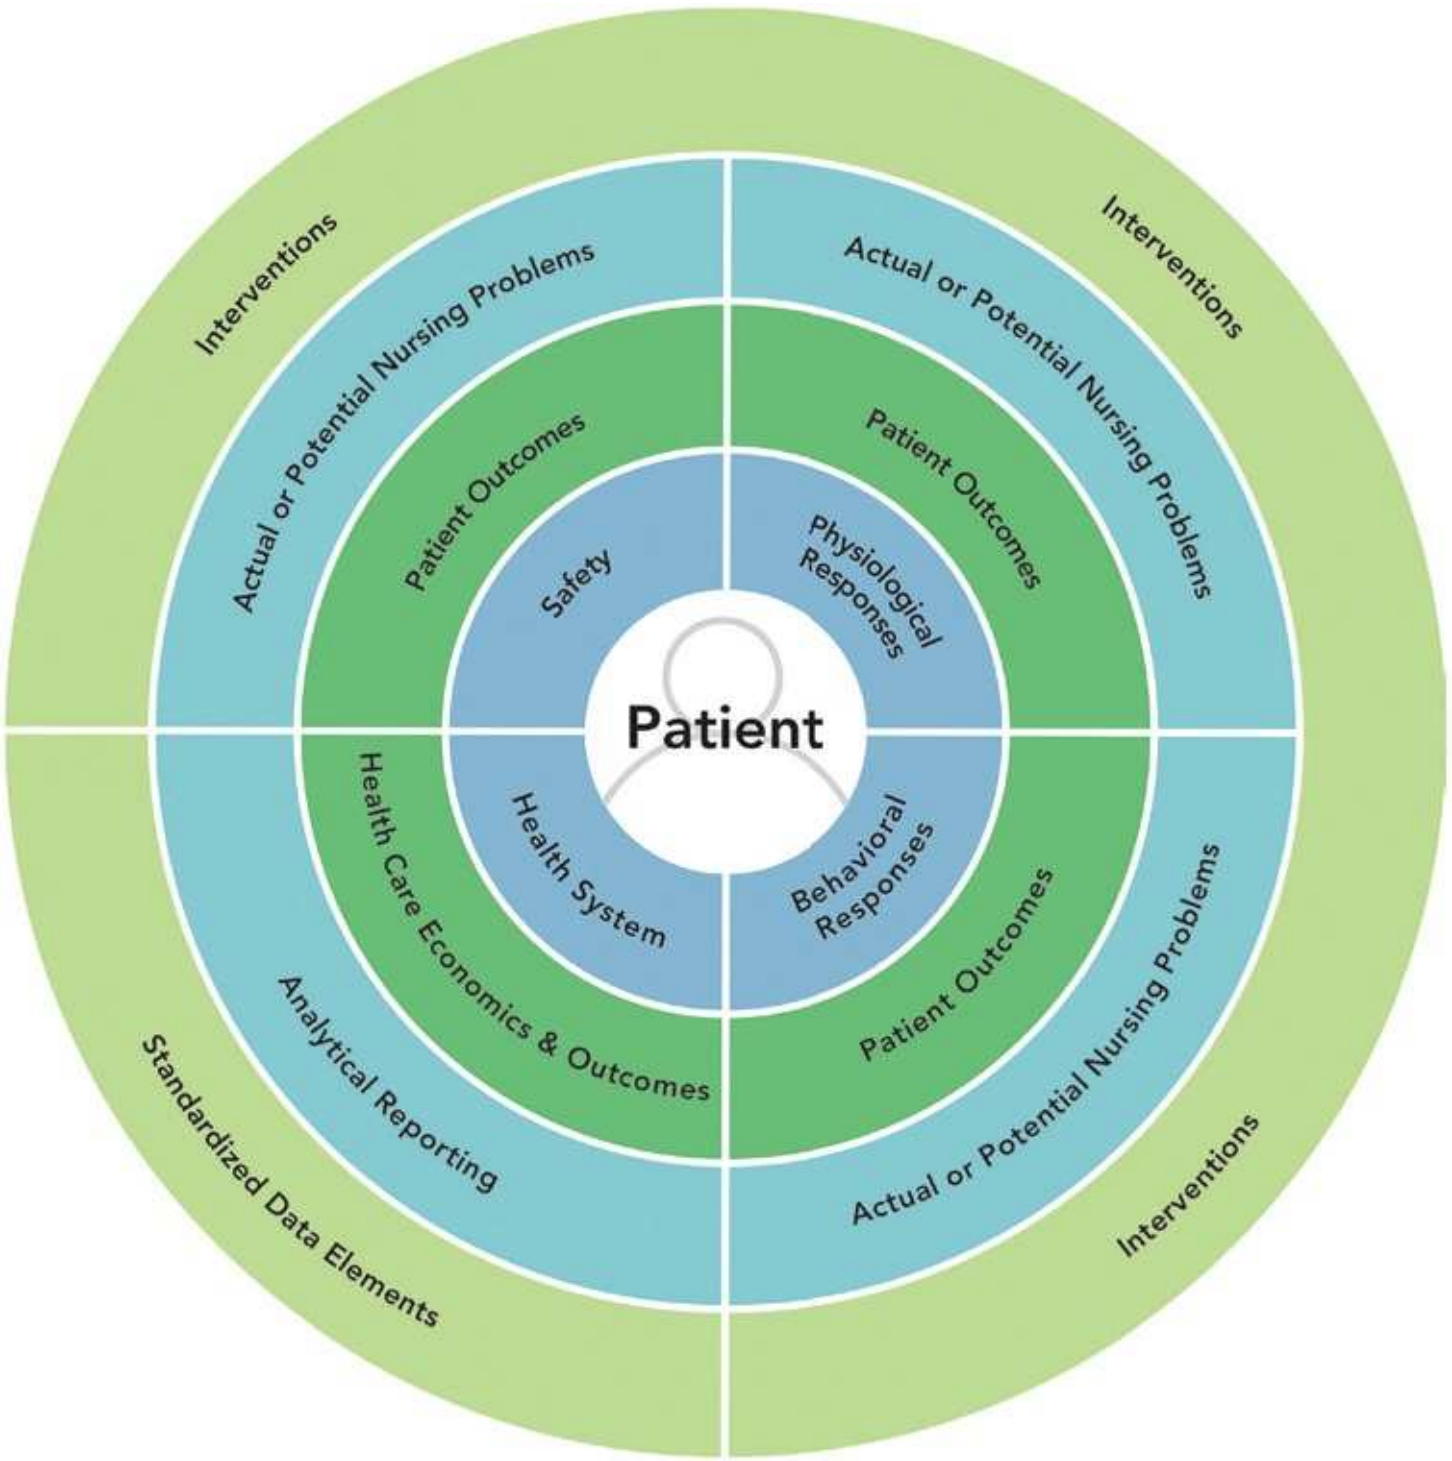

FIGURE 31-1. Perioperative Patient-Focused Model. (*Source:* Reprinted with permission from Guidelines for Perioperative Practice. Copyright © 2018, AORN, Inc, 2170 S. Parker Road, Suite 400, Denver, CO 80231. All rights reserved.)

Perioperative Phases

The patient who is having surgery progresses through several distinct periods, called the **perioperative phases**. The three phases of perioperative patient care are:

- *Preoperative phase:* Begins when the patient and surgeon mutually decide that surgery is necessary and will take place; ends when the patient is transferred to the operating room (OR) or procedural bed.
- *Intraoperative phase:* Begins when the patient is transferred to the OR bed; ends with transfer to the **postanesthesia care unit (PACU)**. The PACU is an area often adjacent to the surgical suite designed to provide care for patients recovering from anesthesia or moderate sedation/analgesia.
- *Postoperative phase:* Begins with admission to the PACU or other recovery area; ends with complete recovery from surgery and the last follow-up health care provider visit.

The postoperative phase can be further divided into phases that represent levels of care, not necessarily locations: (1) phase I, where close monitoring is required for management of airway, ventilation, hemodynamic monitoring, fluid and electrolyte balance, and pain control; (2) phase II, where the patient no longer requires acute care measures and is prepared for self-care, for family/caregiver care, or for care in an extended care environment (e.g., rehabilitation center); and (3) phase III (Extended Care) where the focus is on providing ongoing care for patients requiring extended

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

observation or intervention after transfer or discharge from phase I or II (American Society of PeriAnesthesia Nurses [ASPAN], 2020).

With the increasing trend toward short-stay or same-day surgery, nursing interventions in each phase of perioperative nursing care may vary somewhat, but they remain basically the same. The nursing process is used during each phase to meet physical and psychosocial needs and to facilitate the patient's return to health. Each of these phases, with related patient needs and nursing activities, is described in detail in this chapter.

Surgical Procedure Classification

Surgical procedures usually are classified according to urgency, risk, and purpose. Table 31-1 lists each classification, with purposes and examples for each. No matter what the defined degree of risk, any surgical procedure imposes physical and psychological stress, and is seldom considered minor by the patient.

Recall **Molly Greenbaum**, the 38-year-old woman who is to undergo a vaginal hysterectomy. The nurse would incorporate knowledge about the various classifications of surgery to plan appropriate care before and after surgery.

Table 31-1 Classification of Surgical Procedures

CLASSIFICATION	PURPOSE	EXAMPLES
Based on Urgency		
Elective: Delay of surgery has no ill effects; can be scheduled in advance based on patient's choice	• To remove or repair a body part • To restore function • To improve health • To improve self-concept	Tonsillectomy, hernia repair, cataract extraction and lens implantation, hemorrhoidectomy, hip prosthesis (may also be urgent), scar revision, facelift, mammoplasty
Urgent: Usually done within 24–48 hours	• To remove or repair a body part • To preserve or restore health	Removal of gallbladder, coronary artery bypass graft (CABG), surgical removal of a malignant tumor, colon resection, amputation
Emergency: Done immediately	• To prevent further tissue damage • To preserve life (plus purposes listed above)	Control of hemorrhage; repair of trauma, perforated ulcer, intestinal obstruction; tracheostomy
Based on Degree of Risk		
Major: May be elective, urgent, or emergency	• To preserve life • To remove or repair a body part • To restore function • To improve or maintain health	Carotid endarterectomy, cholecystectomy, nephrectomy, colostomy, hysterectomy, radical mastectomy, amputation, trauma repair, CABG
Minor: Primarily elective	• To remove skin lesions • To correct deformities	Tooth extraction, removal of warts, skin biopsy, dilation and curettage, laparoscopy, cataract extraction, arthroscopy

Based on Purpose		
Diagnostic	• To make or confirm a diagnosis	Breast biopsy, laparoscopy, exploratory laparotomy
Ablative	• To remove a diseased body part	Appendectomy, subtotal thyroidectomy, partial gastrectomy, colon resection, amputation
Palliative	• To relieve or reduce intensity of an illness; is not curative	Colostomy, nerve root resection, debridement of necrotic tissue, tumor debulking, arthroscopy
Reconstructive	• To restore function to traumatized or malfunctioning tissue may also improve self-concept	Scar revision, plastic surgery, skin graft, internal fixation of a fracture, breast reconstruction
Transplantation	• To replace organs or structures that are diseased or malfunctioning	Kidney, liver, cornea, heart, joints
Constructive	• To restore function in congenital anomalies	Cleft palate repair, closure of atrial–septal defect

Surgery Based on Urgency

Surgery based on urgency is further categorized into broad categories that cross specialty areas:

- **Elective surgery** is a procedure that is preplanned and based on the patient's choice and availability of scheduling for the patient, surgeon, and facility. This is a nonurgent procedure that does not have to be done immediately.
- **Urgent surgery** must be done within a reasonably short time frame to preserve health but is not an emergency.
- **Emergency surgery** must be done immediately to preserve life, a body part, or function.

Surgery Based on Degree of Risk

Surgery is classified as minor or major based on the degree of risk for the patient. Minor surgery is almost always performed in settings such as a health care provider's office, an outpatient clinic, or a same-day/outpatient surgery setting (also referred to as ambulatory surgery). This classification means that the surgical procedure usually carries a low risk and results in few complications. In contrast, major surgery may require hospitalization and specialized care, has a higher degree of risk, involves major body organs or life-threatening situations, and has a greater risk for postoperative complications.

However, this major and minor nomenclature is not as descriptive of actual procedures today because of the remarkable evolution of surgical science and technology. Advances in the use of laser techniques and minimally invasive approaches, involving very small incisions, make major surgery less traumatic, which facilitates shortened hospital stays. New surgical approaches using minimally invasive techniques and robotic technology continue to evolve. Thus, many surgical procedures, even though they are classified as major, are now performed on an outpatient (same-day/ambulatory) basis or as a 23-hour hospital stay. Major procedures can be accomplished in short time frames. The patient can return home on the same day with nominal pain, allowing a quick return to normal daily activities.

Surgery Based on Purpose

Surgery may also be classified according to its purpose. Some terms used to classify surgical procedures based on purpose include *diagnostic, curative, preventive, ablative, palliative, reconstructive, transplantation,* and *constructive* (see Table 31-1).

Anesthesia

Anesthesia is a method and technique of making potentially uncomfortable interventions tolerable and safe. Anesthetic agents can be administered systemically (to the whole body) or regionally (to a specific region of the body) to block nerve conduction. General, or systemic, anesthesia is a balance of loss of consciousness, analgesia (pain relief), relaxation, and loss of reflexes (temporary paralysis). In contrast, regional anesthesia does not cause narcosis (sleepiness), but results in analgesia and reflex loss. Moderate sedation involves intravenous (IV) administration of sedatives and analgesics to produce analgesia and a degree of amnesia that can be promptly reversed, whereas topical or local anesthesia targets a specific tissue of the body. Anesthesiologists (medical doctors) or certified registered nurse anesthetists (CRNAs) administer anesthetic agents while monitoring the patient's physiologic response and maintaining homeostasis throughout the procedure and recovery. Nurse anesthesia is an advanced nursing specialty. Both physicians and nurses who administer anesthesia perform preoperative physical assessments, conduct preoperative teaching,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

administer anesthesia during the surgical procedure, and oversee the patient's postoperative recovery from the anesthetic. The pre-anesthetic evaluation (PAE) performed to assess medical readiness of a patient for surgery, may be performed in-person or remotely. The PAE routinely includes an evaluation of the patient's airway, a review of any laboratory or other diagnostic results, and a risk analysis. Early identification of an airway that may be difficult to manage allows for adequate preparation of equipment, the patient, and the interprofessional team (Apfelbaum et al., 2022). Advances in telehealth make the PAE using telehealth technology a reliable and resource-effective option that promotes patient satisfaction, especially for patients who reside in remote or rural areas (Schoen & Prater, 2019).

General (Systemic) Anesthesia

General anesthesia involves the administration of drugs by inhalation or the IV route to produce central nervous system depression. General anesthesia typically is a combination of both IV and inhalation anesthetics that allows for rapid induction, excretion, and reversal of effects. The desired actions of general anesthesia are loss of consciousness, amnesia (short-term loss of memory), analgesia (the brain does not respond to pain signals), relaxed skeletal muscles, and depressed reflexes. Choices of route and type of anesthesia are made primarily by the anesthesia provider after discussion with the patient. Many factors influence these choices, including the type and length of surgery and the physical and psychological status of the patient. For example, children, especially those who are uncooperative, may benefit from inhalation induction. Caregiver presence during induction varies and requires additional education and support of the caregiver (Nelson et al., 2018).

The three phases of general anesthesia are induction, maintenance, and emergence. Induction begins with administration of the anesthetic agent and continues until the patient is ready for the incision. Maintenance continues from this point until near the completion of the procedure. Emergence starts as the patient begins to awaken from the altered state induced by the anesthesia and usually ends when the patient is ready to leave the OR; the length of time depends on the depth and length of anesthesia. New anesthetic agents enable patients to emerge from anesthesia and *wake up* in a fraction of the time required in the past. When these agents are used, patients frequently bypass PACU stage 1 and move directly to PACU stage 2. This is referred to as *fast tracking*. This enables more surgical procedures to be safely done in health care providers' offices and in other ambulatory settings.

General anesthesia is advantageous because it can be used for patients of any age and for any surgical procedure, with the patient unaware of the physical trauma of the surgery. There are, however, major associated risks for circulatory and respiratory depression, postoperative nausea and vomiting (PONV), and alterations in thermoregulation. Postoperative bronchospasm is another risk, especially in patients with multiple comorbidities.

Children and young adults require greater attention as they emerge from general anesthesia because they may experience emergence agitation or emergency delirium. Evidence-based interventions to prevent or combat pediatric emergence agitation include monitoring with advanced technology, involving the family/caregiver(s) in the process, considering pharmacologic adjuncts, and using alternative methods of general anesthesia (Hoch, 2019).

Remember **Marcus Benjamin**, the 73-year-old male who had a total hip replacement. When developing an appropriate care plan for this patient, the nurse would need to incorporate knowledge about the risks associated with general anesthesia along with knowledge of the physiologic changes associated with aging. Key to this care plan would be measures that prevent or minimize Mr. Benjamin's risk for complications.

Moderate Sedation/Analgesia

Moderate sedation/analgesia, also called *conscious* or *procedural sedation,* is used for short-term and minimally invasive procedures. The patient maintains cardiorespiratory function and can respond to verbal commands. The IV administration of sedatives and analgesics (or sedatives alone) produces a decrease in anxiety and discomfort/pain with some degree of amnesia (AORN, 2020). In moderate sedation/analgesia, the patient does not have large variations in vital signs and retains protective reflexes, spontaneous ventilation, and the ability to communicate, including the ability to purposefully respond to verbal and tactile stimulation (AORN, 2020). In addition to anesthesiologists and CRNAs, others who may administer moderate sedation/analgesia include: perioperative, endoscopy, interventional radiology, interventional cardiology, or other nurses with specialized training and competence in administering the medications and monitoring the patient's cardiac rate and rhythm, respiratory rate, oxygen saturation, level of consciousness, level of pain, blood pressure, and skin condition.

Regional Anesthesia

Regional anesthesia occurs when an anesthetic agent is injected near a nerve or nerve pathway in or around the operative site, inhibiting the transmission of sensory stimuli to central nervous system receptors. Pneumatic tourniquets may also be used to confine an intravenous anesthetic to a specific extremity, thus providing anesthesia only to that extremity (AORN, 2020). The patient receiving regional anesthesia remains awake but loses sensation in a specific area or region of the body. In some instances, reflexes may also be lost. Although regional anesthesia may be selected for numerous types of surgery and patients, it is especially useful in reducing postsurgical pain, bowel dysfunction, and length of hospital stay for older adult patients. It also reduces risks associated with general anesthesia for this population.

Regional anesthesia may be accomplished through nerve blocks, spinal anesthesia (subarachnoid block), epidural anesthesia, or intravenous (IV) anesthesia with pneumatic tourniqueting:

- *Nerve blocks* (peripheral) are accomplished by injecting a local anesthetic around a nerve trunk supplying the area of surgery such as the jaw, face, or extremities. Onset and duration of the block depend on the anesthetic drug, its concentration, the amount injected, and the addition of additional medications (such as epinephrine) that prolong the block.
- *Spinal anesthesia* is achieved by injecting a local anesthetic into the subarachnoid space through a lumbar puncture, causing sensory, motor, and autonomic blockage. This type of anesthesia is used for surgery of the lower abdomen, perineum, and legs. Adverse effects of spinal anesthesia may include hypotension, headache, and urine retention.
- *Epidural anesthesia* involves the injection of the anesthetic through the intervertebral spaces, usually in the lumbar region (although it may also be used in the thoracic or cervical regions). It is used for surgeries of the chest, abdomen, pelvis, and legs; epidurals are also commonly used in childbirth.
- *Intravenous anesthesia with pneumatic tourniqueting* primarily occurs with surgery or procedures involving an extremity. The equipment consists of a tourniquet cuff, tubing, and a pressure regulator. Risks include nerve injuries, skin integrity issues, pain, compartment syndrome, formation of a deep vein thrombosis, and systemic issues that may occur with deflation (AORN, 2020).

Local and Topical Anesthesia

Local anesthesia is the injection of an anesthetic agent such as bupivacaine, lidocaine, or tetracaine to a specific area of the body (AORN, 2020). It bathes the tissue around a targeted nerve or infiltrates the underlying tissue in the operative area. The surgeon administers local anesthesia for minor, short-term surgical, or diagnostic procedures such as tissue biopsy. Epinephrine may be mixed with the local anesthetic to minimize bleeding by causing local vasoconstriction. It also prolongs the length of analgesia by trapping the anesthetic in the tissue through slowed absorption that results from the vasoconstriction of the surrounding vessels (AORN, 2020). Local anesthesia may also be injected during general anesthetic procedures to prolong pain relief after the general anesthetic wears off.

Topical anesthesia is primarily applied to intact skin but may be used with mucous membranes and in some cases of wound care. Although its use as a topical anesthetic has declined since its introduction in the 1890s, cocaine in a 4% to 10% solution may be used topically in the mouth, larynx, or nasal cavities alone or in combination with other agents (Gwinnutt & Gwinnutt, 2017; Sikka et al., 2015). Other common topical anesthetics include lidocaine, tetracaine, and benzocaine. A lidocaine (2.5%)–prilocaine (2.5%) combination, frequently referred to as EMLA (eutectic mixture of local anesthetics), may be used on intact skin prior to injection, catheter placement, or laceration repair (Gwinnutt & Gwinnutt, 2017; Sikka et al., 2015). Topical anesthetics may be sprayed, spread, or applied with a compress of drug-saturated gauze or cotton-tipped applicators. Loss of feeling and sensation occur in the specific area where the topical anesthesia is applied.

Informed Consent and Advance Directives

Informed consent reflects a *process* of effective communication that results in the patient's voluntary agreement to undergo a particular procedure or treatment (such as surgery). In order to ensure the patient's understanding prior to giving consent, the health care provider performing the procedure should provide the following information in everyday language that considers the patient's health literacy level and is culturally sensitive (The Joint Commission, 2022):

- Description of the procedure or treatment (its name, site, and side if applicable), potential alternative therapies, and the option of nontreatment
- Underlying disease process and its natural course
- Name and qualifications of the health care provider performing the procedure or treatment—provide an emphasis on shared decision making between the patient and provider(s)
- Explanation of the risks (nature, magnitude, probability of the risks) and benefits
- Explanation that the patient has the right to refuse treatment and that consent can be withdrawn
- Explanation of expected (not guaranteed) outcome, recovery, and rehabilitation plan and course

Informed consent protects the patient, the health care providers, and the health care facility. The signed, dated, and timed form is a legal document as well as an ethical imperative. Regulatory bodies also consider the *quality* of informed consent as it relates to patient autonomy and other ethical and legal principles, and have implemented the use of a validated tool to assess the quality of informed consent documents (Centers for Medicare & Medicaid Services, 2020;

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Spatz et al., 2020). More detailed information about informed consent is included in Chapter 7.

Concept Mastery

Knowing the key elements of the informed consent *process* improves the *quality* of the informed consent as it relates to patient autonomy, the role of the nurse, and other ethical and legal considerations.

Advance directives, which are also legal documents, allow patients to specify instructions for health care treatment should they be unable to communicate these wishes postoperatively. This allows patients to discuss their wishes with family members in advance of the surgery. Suspension of a do-not-resuscitate (DNR) or allow-natural-death (AND) order, although not required for surgery, should be discussed as part of the informed consent process. Actions used in resuscitation (mechanical ventilation, vasoactive drips) are integral to the surgical process, and surgery itself poses specific risks where reversible cardiopulmonary arrest may occur (American Society of Anesthesiologists, 2018; Shapiro & Singer, 2019). It is important to discuss and document the exact wishes of the patient before surgery, especially related to resuscitation. See Chapter 44 for more information on advance care planning.

Outpatient/Same-Day Surgery

Surgical procedures performed in outpatient or same-day surgical settings are common. These include freestanding surgery centers, hospital-based surgery centers, interventional units, and health care providers' offices. Some freestanding surgery centers specialize in selected types of surgery, such as orthopedics, repair of cataracts, or hernia repair. Others perform a wide variety of surgical interventions, including major surgical procedures that formerly required a stay in a hospital.

Typically, patients are admitted to the ambulatory surgery center the morning of surgery. Allowing the patient to spend the night before surgery at home and to return home to recover reduces much of the stress associated with surgery and may also decrease the risk of infection. Patients who are older, chronically ill, or who do not have support systems or access to resources to provide the care needed after surgery may require additional teaching and referral for home care services. When possible, the nurse should arrange these types of referrals prior to the date of surgery.

NURSING PROCESS FOR PREOPERATIVE CARE

Patients who require surgical intervention and nursing care enter the health care setting due to a wide variety of situations, ranging from essentially healthy people who have planned elective procedures to emergency admissions for treatment of trauma or serious illness. Surgical patients may be of any age and at any point on the health–illness continuum. It is the nurse's responsibility to identify factors that affect the risk of a surgical procedure. This includes assessing the physical and psychosocial needs of the patient and family, diagnosing actual or potential health problems or needs, and establishing a plan of care. Interventions are designed to meet the patient's physical and psychological needs and facilitate recovery as the patient progresses through the perioperative period.

Box 31-1 Preoperative Information for Outpatient/Same-Day Surgery

Using simple language the patient can understand, instruct the patient (verbally and in writing) as follows:

- List medications routinely taken and ask the health care provider which should be taken or omitted the morning of surgery.
- Notify the surgeon's office if a cold or infection develops before surgery.
- List all allergies and be sure the OR staff is aware of them.
- Follow all instructions from your surgeon regarding bathing or showering with a special soap or solution.
- Remove nail polish and, depending on the surgical site, do not wear makeup, lotions, or deodorant on the day of the procedure.
- Leave all jewelry and valuables at home.
- Wear clothing that buttons in front; short-sleeved garments are better for surgery on the hands.
- Have a responsible adult available for transportation home after recovery from anesthesia.
- Inform the patient of limitations on eating or drinking before surgery, with a specific time to begin the limitations.
- Notify the patient about when and where to arrive for the procedure, as well as the estimated time when the procedure will be performed.

Consider **Gabrielle McAllister**, the 5-year-old child scheduled for tonsillectomy and adenoidectomy. As a child with a history of cardiac defects, prior surgeries, and latex allergy, she is at risk for anesthesia complications related to her congenital disability and allergic reaction if exposed to latex. The nurse would need to obtain a thorough history of her previous surgeries, what happens when she is exposed to latex, and how she responded after the surgeries to identify her risk for problems with the current surgical procedure and anesthesia.

Some outcomes that frame plans of care for surgical patients might include that patients:

- Receive respectful care that is developmentally and culturally appropriate
- Remain free from injury and adverse effects related to positioning, retained surgical items, or chemical, physical, or electrical hazards
- Experience no surgical site infection(s)
- Maintain fluid and electrolyte balance and skin integrity
- Maintain normal body temperature
- Collaborate in the management of their pain
- Demonstrate an understanding of the physiologic and psychological responses to their planned surgery
- Participate in their rehabilitation process following surgery

Assessing

The importance of preoperative assessment cannot be overemphasized. Surgery causes major trauma to the body, and preoperative assessments identify factors that may place the patient at greater risk for complications during and after surgery.

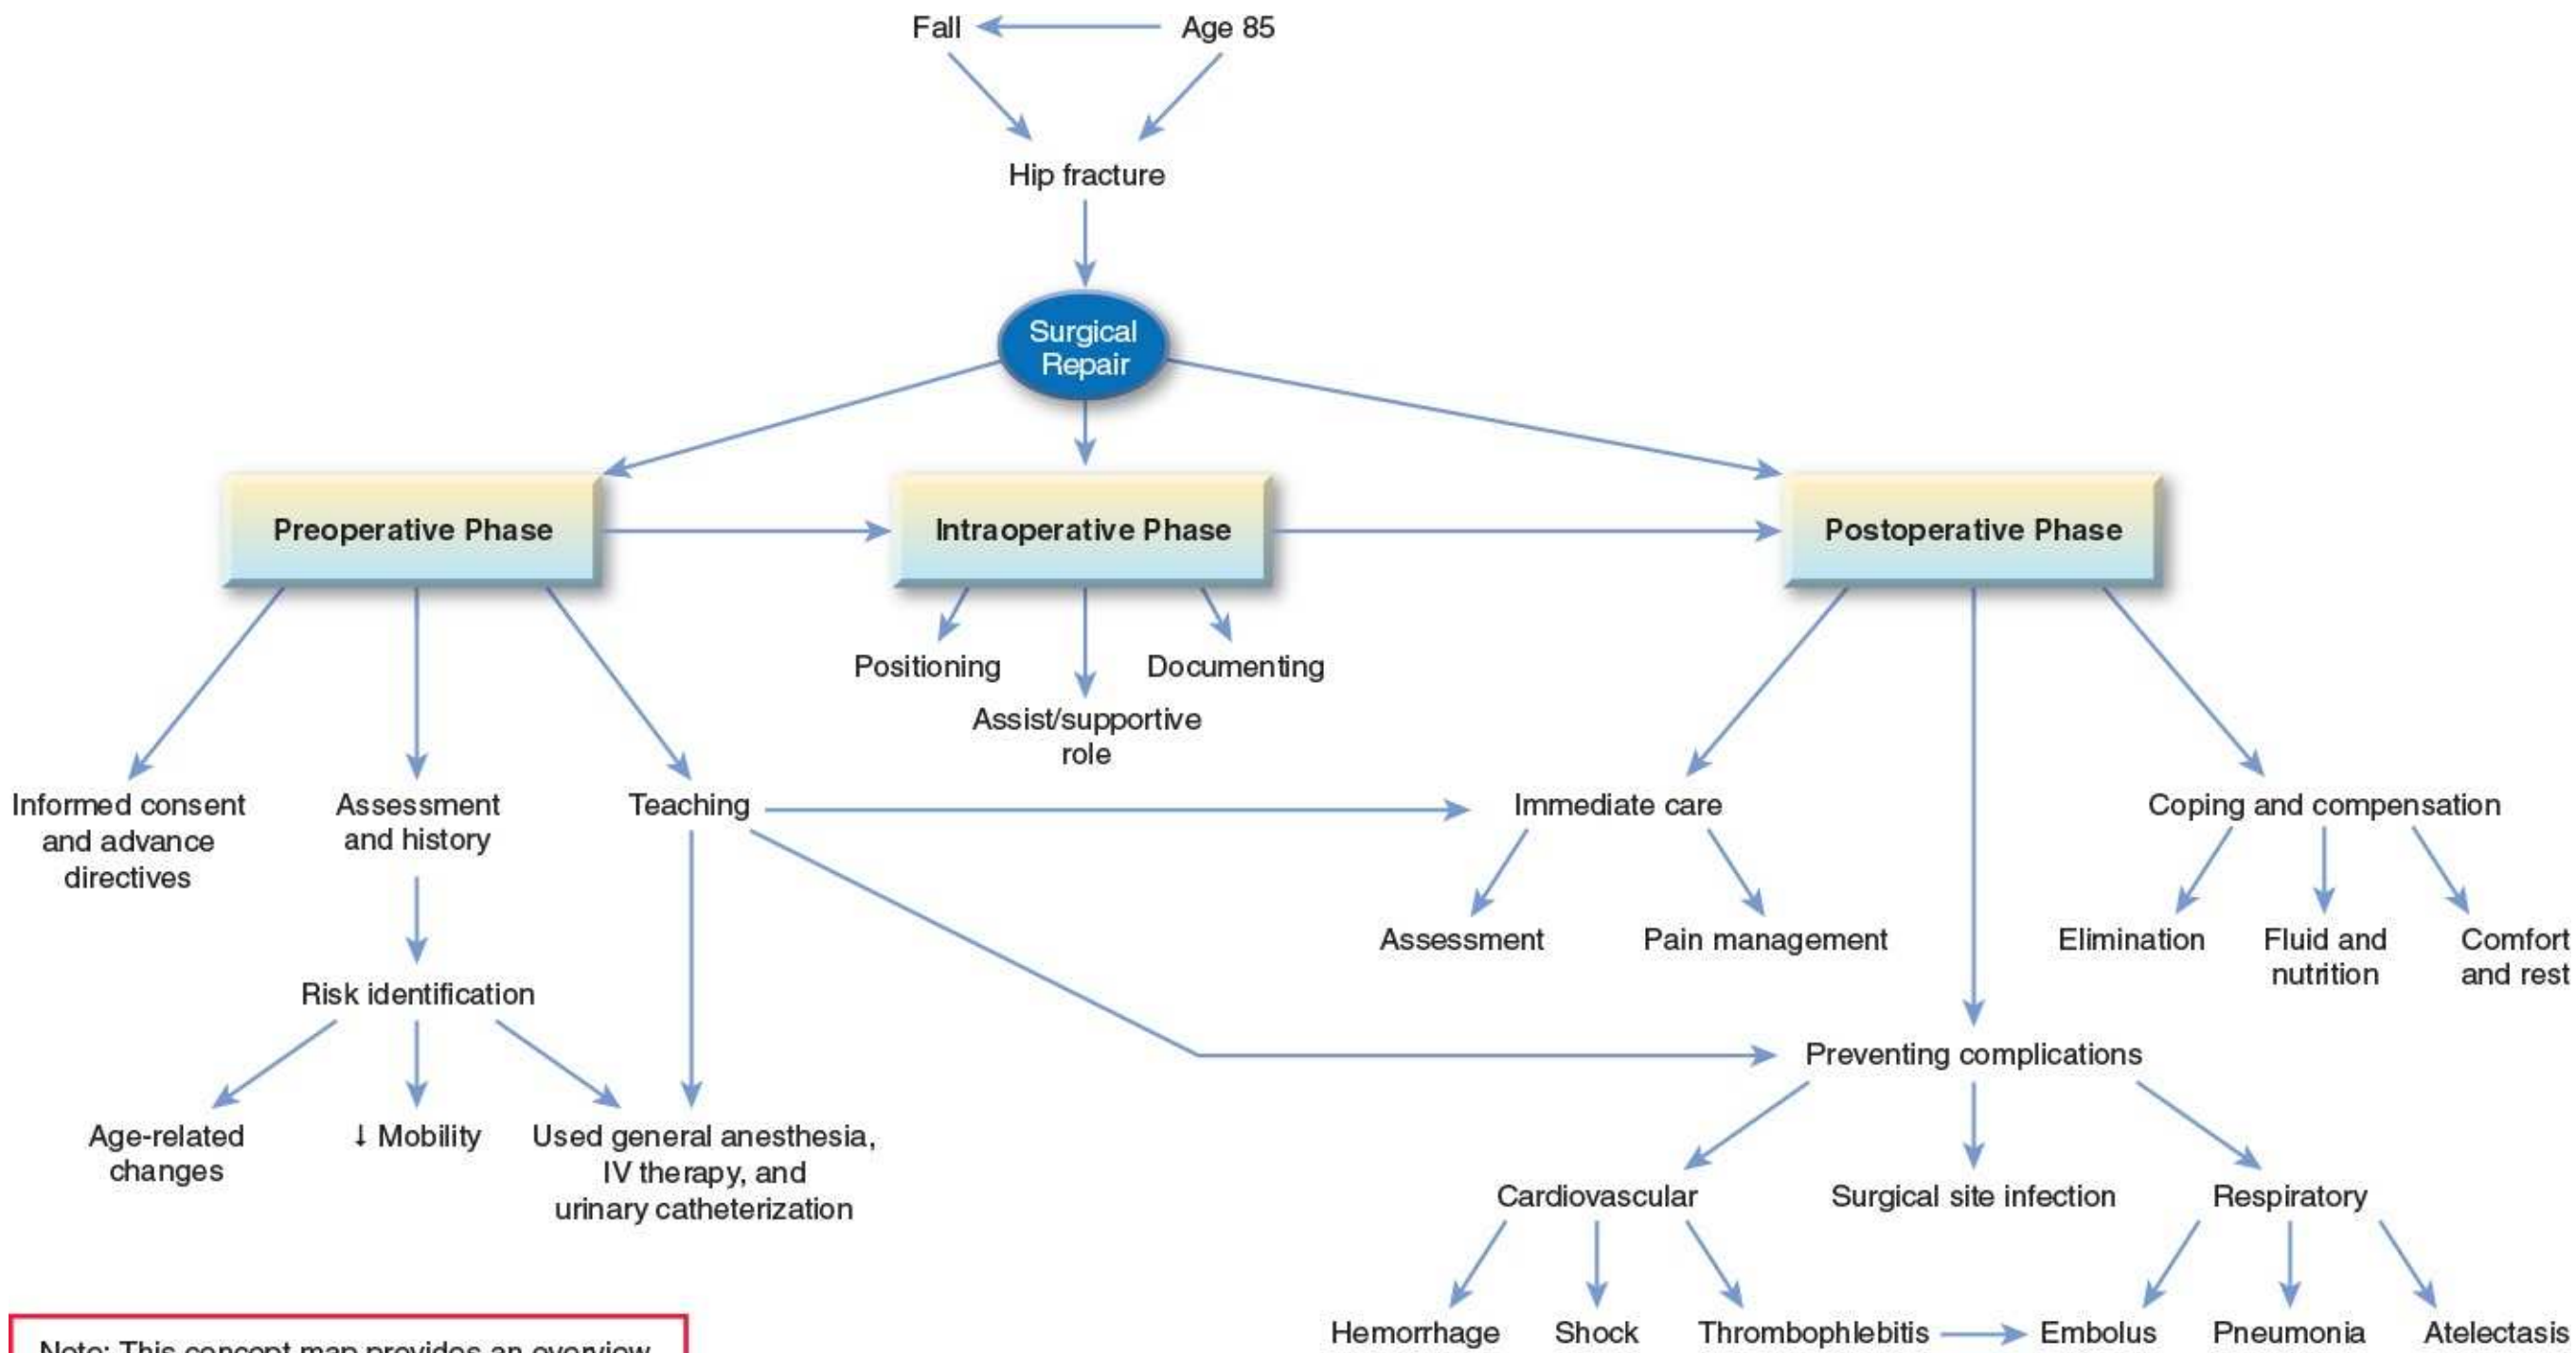
Assessment of the surgical patient includes:

- Obtaining a health history and performing a physical assessment to establish a baseline database
- Identifying risk factors and allergies that could cause surgical adverse events
- Identifying medications and treatments the patient is currently receiving
- Determining the teaching and psychosocial needs of the patient and caregivers
- Determining postsurgical support and referral needs for recovery

The assessment is often conducted several days before surgery as part of preoperative laboratory screening and teaching; this is referred to as preadmission testing. It may be conducted in the hospital, a surgical clinic, an office, in the patient's home, or by phone.

Preoperative nursing assessments and teaching are key care activities for patients who will be having outpatient or same-day surgery. Preoperative teaching can often be combined with preoperative screening tests, which are usually done up to 30 days before the scheduled surgery. Preoperative assessment and teaching for outpatient/same-day surgery includes providing important information and preoperative instructions to the patient and family (Box 31-1).

Unfolding Patient Stories: Edith Jacobson • Part 1



Edith Jacobson, an 85-year-old female, is scheduled for surgical repair of a left hip fracture under general anesthesia. What are the responsibilities of the nurse in the preoperative period to prepare the patient for surgery and minimize the risk of complications? What preoperative teaching should the nurse provide for Edith and her family?

(Edith Jacobson's story continues in Chapter 35.) Care for Edith and other patients in a realistic virtual environment: *vSim for Nursing* (thepoint.lww.com/vSimFunds). Practice documenting these patients'

The health history identifies risk factors and strengths in the patient's physical and psychosocial status, and helps the nurse individualize the preoperative assessment. Health history information significant to the surgical experience includes the patient's developmental level; medical history, including allergies; medication history, including nonprescription drugs; previous surgeries; implants; extremity limitations; perceptions and knowledge of the surgery to be done; nutrition; use of alcohol, illicit drugs, or nicotine; activities of daily living and occupation; coping patterns and support systems; and sociocultural needs.

DEVELOPMENTAL CONSIDERATIONS

Surgery poses a greater risk for infants and older adults than for older children and young or middle-aged adults. The infant has a lower total blood volume, making even a small loss of blood a serious concern because of the risk for dehydration and the inability to respond to the need for increased oxygen during surgery. Due to infants' small, soft, and pliable airways and their propensity for developing upper respiratory infections, they can quickly develop airway obstruction, bronchospasm, and stridor that can result in hypoxia and even respiratory failure. If an infant or young child exhibits signs of even mild respiratory infection on the day of surgery, the procedure might be postponed until a later date.

Infants also have difficulty maintaining stable body temperature during surgery because the shivering reflex is not well developed, making hypothermia or hyperthermia more likely. Their lower glomerular filtration rate and creatinine clearance can lead to a slower metabolism of drugs that require renal biotransformation. Because the liver is immature until after the first year of life, the effects of muscle relaxants and narcotics may be prolonged.

Physiologic changes associated with aging (described in Chapter 24) increase the surgical risk for older adults. These changes, summarized in the Focus on the Older Adult box, decrease the ability of older adults to respond to the stress of surgery, alter the effects of preoperative and postoperative medications and anesthesia, and prolong or alter wound-healing processes. With an increasing older adult population, assessing physiologic changes is crucial to providing safe, quality nursing care to older surgical patients. Chronic illnesses, more common in the older population, also increase surgical risk and may require alterations in usual perioperative procedures. For example, a patient with heart failure may be more easily fatigued and thus unable to be mobile immediately after surgery.

Consider **Marcus Benjamin**, the 73-year-old male who had a total hip replacement. Due to his age, the nurse would need to be alert to potential complications specifically associated with age-related changes, reduced mobility, and surgical equipment.

MEDICAL HISTORY

The medical history provides information about past and current illnesses. Pathologic changes associated with past and current illnesses increase surgical risk as well as the risk for postoperative complications. Preoperative assessments and documentation are necessary to provide a database for individualized assessments and interventions in the intraoperative and postoperative phases of care. Examples of diseases and associated risks may include:

- Cardiovascular diseases—such as thrombocytopenia, hemophilia, recent myocardial infarction or cardiac surgery, heart failure, and dysrhythmias—increase the risk for anesthesia complications, including hemorrhage and hypovolemic shock, hypotension, venous stasis, thrombophlebitis/thromboembolism, and overhydration with IV fluids.
- Respiratory disorders—such as pneumonia, bronchitis, asthma, emphysema, and chronic obstructive pulmonary diseases—increase the risk for respiratory depression from anesthesia as well as postoperative pneumonia, atelectasis, and alterations in acid–base balance.
- Kidney and liver diseases influence the patient's response to anesthesia, affect fluid and electrolyte as well as acid–base balance, alter the metabolism and excretion of drugs, and impair wound healing.
- Endocrine diseases, especially diabetes mellitus, increase the risk for hypoglycemia or acidosis, slow wound healing, and present an increased risk for postoperative cardiovascular complications.

SURGICAL HISTORY

Gathering data about previous surgeries is important for meeting the patient's physical and psychological needs throughout the perioperative period. Physical implications of previous surgeries are important to the intraoperative and

postoperative phases (e.g., previous heart or lung surgery may necessitate adaptations in anesthesia and in positioning during surgery). Previous surgical complications—such as malignant hyperthermia, latex sensitivity, pneumonia, thrombophlebitis, or **deep vein thrombosis (DVT)**, a formation of a blood clot (thrombus) in a deep vein or surgical site infection—may put the patient at risk during this surgery, necessitating vigilant intraoperative and postoperative monitoring.

The patient's past experiences with surgery also affect the plan of care established in the preoperative phase, especially if a past experience was negative. When the interview elicits negative feelings about the surgical experience, pain management, or nursing interventions carried out to prevent complications during previous surgeries, teaching and mutual goal setting become even more important. For children, stressful events before surgery include the admission process, lab tests, injections, the time frame before and during transport to the OR, and the recovery period in the PACU.

In addition to experiences with past surgery, the patient's perceptions and knowledge of the upcoming surgical procedure should be assessed. The patient's questions or statements about the surgery are important for meeting psychological and family needs when preparing the patient for surgery, planning for patient and family teaching, and preparing for discharge.

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES IN PERIOPERATIVE PATIENTS

Age-Related Changes	Nursing Strategies
Cardiovascular	
Decreased cardiac output, stroke volume, and cardiac reserve Decreased peripheral circulation Increased vascular rigidity	• Obtain and record baseline vital signs. • Assess peripheral pulses. • Teach leg exercises, turning, and explain the purpose of early ambulation after surgery. • Document baseline activity levels and tolerance of fatigue. • Monitor fluid administration rate. • Allow sufficient time for effects of medications to occur; administer the lowest dose possible of medications.
Respiratory	
• Reduced vital capacity • Diminished cough reflex • Decreased oxygenation of blood • Decreased chest expansion and strength of intercostal muscles and diaphragm	• Obtain and record baseline respiratory depth and rate. • Teach coughing and deep-breathing exercises. • Teach use of incentive spirometer. • Assess color of skin. • Explain use of pulse oximeter for monitoring postoperative oxygenation.
Central Nervous System	
Decreased reaction time and coordination Reduced short-term memory Sensory deficits Decreased thermoregulation ability	• Orient to surroundings. • Institute safety measures, such as keeping environment clear of clutter and using a night-light. • Allow additional time for teaching, *teach-back* activities, and questions and answers. • Use appropriate measures to conserve body heat.
Renal	
Decreased renal blood flow Reduced bladder capacity	• Monitor fluid and electrolyte status. • Maintain and record intake and output. • Provide ready access to toileting.
Gastrointestinal	
Increased gastric pH Prolonged gastric-emptying time Decreased hepatic blood flow and enzyme function	• Obtain baseline weight. • Monitor nutritional status (weight, laboratory data). • Observe for prolonged effects of medications.
Integumentary	

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Decreased vascularity Decreased skin moisture and elasticity Decreased subcutaneous fat	• Assess skin status. • Monitor fluid status. • Pad and protect bony prominences. • Monitor skin for pressure areas. • Use minimal amounts of tape on dressings and intravenous sites. • Encourage active and passive range of motion, with repositioning as needed.

MEDICATION HISTORY

The use of prescribed, over-the-counter, or herbal drugs can affect the patient's reaction to, and increase the risk from, the stress of surgery and the effects of the anesthetic agent. Some herbal products can increase bleeding while others may potentiate the actions of depressant anesthetic drugs. Medications in the following categories increase surgical risk:

- Anticoagulants (may precipitate hemorrhage)
- Diuretics (may cause electrolyte imbalances, with resulting respiratory depression from anesthesia)
- Tranquilizers (may increase the hypotensive effect of anesthetic agents)
- Adrenal steroids (abrupt withdrawal may cause cardiovascular collapse in long-term users)
- Antibiotics in the mycin group (when combined with certain muscle relaxants used during surgery, may cause respiratory paralysis)

Although some medications are discontinued before surgery, the nurse should know the purposes and actions of the patient's drugs as well as the health care provider's orders. Specific medications may be given the morning of surgery with sips of water (e.g., patients with heart or cardiovascular problems or diabetes mellitus).

NUTRITIONAL STATUS

Both malnutrition and obesity increase surgical risk. Surgery increases the body's need for nutrients necessary for normal tissue healing and resistance to infection. A patient who is malnourished is at greater risk for alterations in fluid and electrolyte balance, delay in wound healing, and wound infection. Patients who are obese are at increased risk for respiratory and cardiovascular compromise. The supine position, often used in surgery and other invasive procedures, negatively impacts on airway management, ventilation and oxygenation, pulmonary and cardiac blood flow, cardiac output, and work of the heart. Patients who are obese also have an increased incidence of gastroesophageal reflux disease (GERD), hiatal hernia, and abdominal pressure that puts them at risk for aspiration of stomach contents (AORN, 2020). Adipose tissue has a poor blood supply and, therefore, has less resistance to infection. As a result, postoperative complications of delayed wound healing, wound infection, and disruption in the integrity of the wound are more common.

USE OF ALCOHOL OR ILLICIT/PRESCRIPTION/OTHER DRUGS

Patients with a large habitual intake of alcohol require larger doses of anesthetic agents and postoperative analgesics, increasing the risk for drug-related complications. Although the exact mechanisms remain unclear, patients who use illicit drugs, opioids, or cannabis (tetrahydrocannabinol [THC]) are at risk for interactions with anesthetic agents and often require a multimodal approach for anesthesia (Maslonka et al., 2020). These are specific to the illicit drug used and should be noted on the medical record for safe anesthetic management. IV drug use may render veins hardened, inflamed, and unusable for anesthesia drug administration.

Patients who smoke or use electronic nicotine delivery systems (ENDS)/vaping products (ASPAN, 2020) are at higher risk for respiratory complications after surgery. All patients retain pulmonary secretions during anesthesia, but smokers, who already have increased mucous secretions and decreased ciliary action in the tracheobronchial tree, have more difficulty clearing the respiratory passages after surgery. In addition, the tracheobronchial mucosa is chronically irritated in people who smoke; anesthesia increases this irritation. Patients who smoke are at risk for hypoxia and postoperative pneumonia. Nicotine compromises wound healing by constricting blood vessels, impairing blood flow to healing tissues.

ACTIVITIES OF DAILY LIVING AND OCCUPATION

Exercise, rest, and sleep habits are important for preventing postoperative complications and facilitating recovery. A patient with a well-established exercise program has improved cardiovascular, respiratory, metabolic, and musculoskeletal function, which decreases the risks of surgery. Rest and sleep are essential to physical and emotional adaptation and recovery from the stress of surgery. Information from the health history allows the nurse to individualize interventions to promote rest and sleep.

Many surgical procedures require a delay in returning to a career/occupation/job or may affect how the patient

earns a living. Knowledge of a patient's usual work and their concerns about returning to work helps the nurse plan necessary teaching and referrals.

COPING PATTERNS AND SUPPORT SYSTEMS

Assessing the patient's psychological, sociocultural, and spiritual dimensions is as important as the physical history and examination. Surgery is a major psychological stressor and affects coping patterns, support systems, and individual human needs. A surgical procedure, even a planned, minor procedure, can cause anxiety and fear. While obtaining the health history, the nurse uses cues from the patient's and family's verbal and nonverbal communication to identify fears and concerns, and to plan nursing interventions to provide the information and emotional support necessary for successful recovery from surgery.

Surgery is an unfamiliar experience over which a person has no control; the resulting anxiety and fear may be expressed in many ways such as anger, withdrawal, apathy, confrontation, or questioning. Patients often fear the unknown, pain or death, and changes in body image and self-concept. The patient typically has fears about the surgery itself—the anesthesia, the diagnosis, the future, financial and family responsibilities, response to pain, or possible disfigurement or disability. Common fears are that the anesthesia will not "put me to sleep," that death will occur during surgery, or that the patient will not be able to handle postoperative pain. Surgical procedures may leave the patient with permanent changes in body structure, function, or appearance. This may increase patients' fear of alterations in physical attractiveness, social relationships, lifestyle, and sexuality.

Remember **Molly Greenbaum**, the 38-year-old female who is fearful of surgery? Her statements about the inability to sleep, in conjunction with the tears in her eyes and wringing of hands, would be cues that she is experiencing stress. Exploring Molly's fears, past coping mechanisms, and support systems would be valuable in developing the patient's plan of care, both before and after surgery. Doing so would help promote a positive perioperative experience for her. In addition, the nurse would need to investigate what specific trepidation Molly may be experiencing related to a vaginal hysterectomy, such as changes in physical attractiveness, marital relationship, sexuality, and end of reproductive capability.

Therapeutic communication skills are essential for establishing the trusting nurse–patient relationship that is necessary to identify and resolve fear. Encourage the patient to identify and verbalize fears; often simply talking about fears helps to diminish their magnitude. At the same time, incorrect knowledge can be identified and corrected, strengths can be noted, and teaching can begin. The reduction of anxiety is of major importance in preoperative preparation; emotional stress added to the physical stress of surgery increases the surgical risk. The nursing history should elicit the ways in which a patient provides self-support to reduce stress. These are discussed in Chapter 43 and range from listening to music to practicing active relaxation techniques. See the accompanying Research in Nursing box.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Description of Missed Perioperative Nursing Care

A 2015 comprehensive review found that between 55% and 98% of nurses reported not completing at least one task during their assigned shift on their inpatient hospital unit. This identified missed care ranged from engaging in interprofessional care rounds to performing activities of daily living such as mouthcare or ambulation. Missed care could potentially also have detrimental effects on patient outcomes in the highly acute and well-defined perioperative period.

Related Research

Marsh, V., Kalisch, B., McLaughlin, M., & Nguyen, L. (2020). Nurses' perceptions of the extent and type of missed perioperative nursing care. *AORN Journal*, *112*(3), 237–247. https://doi.org/10.1002/aorn.13146

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

This study used a cross-sectional design with practicing operating room (OR) nurses who were members of their associated professional organization (AORN) to describe their reports of missed perioperative nursing care. The 1,693 participants completed the MISSCARE-OR Survey. This instrument was developed based on the Kalisch and Williams MISSCARE Survey from 2009; revised using published literature, a focus group, individual interviews; and validated through exploratory and confirmatory factor analyses. The five most frequently reported missed perioperative nursing care items were: (a) communication among the interprofessional team prior to transfer to the operating room (43.8%), (b) suspension of activities during the required surgical time out (39.9%), (c) use of isolation precautions for patients with infectious diseases (36.1%), (d) use of a standardized hand-off tool during transitions (33.7%), and (e) the reporting of abnormal laboratory values to the anesthesia provider (33.4%). It is noteworthy that OR nurses who reported adequate staffing reported fewer missed nursing care interventions than OR nurses who reported inadequate staffing.

Relevance to Nursing Practice

The emphasis of the World Health Organization (WHO), The Joint Commission, and AORN recommendations on checklists focused on *safety, closing,* and *legal considerations* may explain why fewer instances of missed care in these areas were reported. Perioperative nursing care items associated with communication were the most frequently reported missed. Education of the interprofessional team and future research needs to focus on strategies to improve communication and investigate the relationship between missed perioperative nursing care and patient surgical outcomes.

Coping with stress can be facilitated through the support systems identified in the assessment phase of preoperative nursing care. When appropriate and approved by the patient, family members or significant others should be part of the initial interview and should be included in discussions of fears and concerns. Encourage family members to provide support before and after surgery. When permitted, encourage parents/guardians to accompany their child to the preoperative waiting area and bring the parents/guardians to the recovery area when the child is awake.

Identifying the patient's spiritual beliefs aids in meeting individual spiritual needs. These needs can be met through acceptance, participation in prayer or other rituals, and/or referral to a spiritual leader. Faith in a higher being or source of personal strength may provide support and help to reduce fear in some people.

The need for other support systems can also be identified in the initial interview. For example, a patient having a colostomy, heart transplant, or mastectomy may have many questions answered and anxieties reduced by a preoperative visit from a person who has had the same operation and adapted successfully.

SOCIOCULTURAL NEEDS

A person's perceptions of and reactions to the surgical experience are influenced by several factors, including family health beliefs and practices, cultural/ethnic background, and social determinants of health. A patient who requires surgery, but lacks the requisite medical literacy and resources, may appear resistant to teaching and exhibit signs of nonadherence. Reactions to teaching, physical care, and pain are also influenced by a patient's background and experience. For example, a patient reared with the belief that it is inappropriate to acknowledge pain may demonstrate a stoic acceptance of pain and refuse needed medications postoperatively. Also keep in mind that a patient who had someone close to them die during the perioperative period may consciously or unconsciously associate the surgical experience with death.

Cultural and ethnic influences also affect the patient's responses to and perceptions of the surgical experience. The patient's cultural background may require that nursing interventions be individualized to meet needs in such areas as language, food preferences, family interactions and participation, personal space, and health beliefs and practices (see Chapter 5). For example, a patient from a culture that believes that bed rest is the most important treatment for illness or injury may have difficulty accepting the need for postoperative exercises and early ambulation. Language barriers require the use of formal interpreter services (not family members) that should be utilized at every phase of the perioperative period.

Focused Assessment Guide 31-1

PREOPERATIVE PHYSICAL ASSESSMENT

Factors to Assess	Questions and Approaches
General survey	• Note general state of health. • Note body posture and stature. • Take and record vital signs.
Integumentary system	• Inspect skin for color, characteristics, and location and appearance of any lesions. • Assess skin over bony prominences. • Determine skin turgor.

Respiratory system	• Observe chest excursion and diameter and shape of thorax. • Auscultate breath sounds. • Palpate for any pain or tenderness.
Cardiovascular system	• Inspect for jugular vein distention. • Auscultate apical rate, rhythm, and character. • Auscultate heart sounds. • Inspect for peripheral edema. • Palpate strength of peripheral pulses bilaterally.
Gastrointestinal system	• Inquire about time of last intake of fluid or food. • Inquire about time of last bowel movement. • Inspect abdominal contour. • Auscultate bowel sounds.
Neurologic system	• Note orientation, level of consciousness, awareness, and speech. • Assess reflexes. • Assess motor and sensory ability. • Assess visual and hearing ability.
Musculoskeletal system	• Inspect and note joint range of motion. • Palpate muscle strength. • Assess ability to ambulate.

Physical Assessment

Assessing the patient's current physical status provides data for interventions to decrease surgical risk and prevent potential postoperative complications. Depending on the situation, the physical assessment is conducted as described in Chapter 27. See also Focused Assessment Guide 31-1 for key areas to assess preoperatively.

Various presurgical screening tests provide objective data of normal body function. In cases of abnormalities, such tests provide data for medical interventions to improve the patient's physical status and thus decrease potential surgical complications. The nurse's role is to ensure that the tests are explained to the patient, appropriate specimens are collected, the results are documented in the patient's record before surgery, and abnormal findings are reported.

Usual presurgical screening tests include chest x-ray, electrocardiography (ECG/EKG), complete blood count (CBC), basic or complete metabolic panel (electrolytes, renal function), and urinalysis. Normal findings for laboratory tests are found in Appendix C. Significant abnormal findings include an elevated white blood cell count (presence of infection), decreased hematocrit and hemoglobin level (presence of bleeding, anemia), prolonged coagulation times (liver or medication-based), hyperkalemia or hypokalemia (increased risk for cardiac problems), and elevated blood urea nitrogen or urinalysis results (potential kidney issues). Additional cardiac clearance may be indicated for patients with a cardiac history or abnormal ECG/EKG results. Glucose testing is done as part of presurgical screening and often repeated the morning of surgery.

Diagnosing Actual or Potential Health Problems and Needs

Patient problems and needs identified in the preoperative period involve actual and potential problems and often focus on safety and mitigation of complications. These problems and needs are derived from the analysis of subjective and objective data obtained from the health history and physical examination as well as information from other health team members and screening tests. The actual and potential health problems and needs identified in the preoperative phase guide the entire perioperative plan of care. Although the plan is individualized, there are some risks and potential problems that exist for any patient undergoing an operative or other invasive procedure. The development and communication of a coordinated plan of care improves interprofessional collaboration and minimizes the risk of complications in the intraoperative and postoperative phases. Examples of patient problems or needs with related etiology and signs and symptoms can be found in the box titled Examples of Actual or Potential Health Problems and Needs: Preoperative Patient.

Examples of Actual or Potential Health Problems and Needs

PREOPERATIVE PATIENT

Actual or Potential Health Problem or Need	Possible Etiologic Factors	Potential Signs and Symptoms
Knowledge Deficiency	• Lack of environmental and situational information regarding impending surgery • Surgical procedure—complexity, classification, preparation • Specific, universal perioperative outcomes	• Asking appropriate/inappropriate questions • Verbalizations of lack of understanding, complex information, processing of new information

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Perioperative Injury Risk	• Alteration in cardiac and/or pulmonary function • Alteration in skin integrity—surgical positioning, immobility • Individualized risk factors—age, lifestyle (smoking, obesity), comorbidities • Stasis of body fluid • Expected and unexpected risks of anesthesia

Outcome Identification and Planning

Preoperative nursing care is affected by the length of the preoperative phase. There may not be enough time for comprehensive assessments and teaching for patients who enter the hospital through the emergency department needing immediate surgery and those who have outpatient/same-day surgery. In such cases, the nurse uses standardized preoperative plans and individualizes the plan for the particular patient and family. Outcomes are standard for all patients having surgery, but nursing interventions are designed to meet the priority needs of individual patients and situations.

Planning for the entire perioperative period is done in the preoperative phase and includes expected outcomes that are discussed and mutually agreed on by the nurse, the patient, and the family. Patient-specific outcomes may include that the patient:

- Verbalizes physical- and emotional-readiness for surgery
- Demonstrates coughing, turning, deep-breathing, and other postoperative exercises
- Verbalizes expectations of postoperative pain management
- Maintains fluid intake and nutritional balance to meet needs

Implementing

Preoperative nursing interventions provide the patient with the necessary psychological and physical preparation for surgery and the postoperative phase. This section discusses implementing the care plan to meet established patient goals. Skill 31-1 (on pages 1069–1074) outlines the actions and rationale for preoperative patient care.

Preoperative nursing care is specific and focused on addressing key aspects of care involving (Turunen et al., 2017):

- **Holistic preoperative screening:** complete medical, physical, social, psychological, and personal assessments
- **Coordination:** collaborate with the entire interprofessional team
- **Communication:** promote open, clear communication
- **Patient and family education:** provide specific pre- and postoperative instructions
- **Individual patient- and family-centered care:** promote empowerment and emotional support/comfort
- **Preoperative contact:** engage with the patient prior to surgery for screening and patient preparation, providing last-minute instruction as needed
- **Scheduling:** prioritize and communicate surgical scheduling plans

Box 31-2	Nursing Interventions to Meet Psychological Needs of Patients Having Surgery

- Practice intentional presence in which the focus is on being in the moment with the patient.
- Establish and maintain a therapeutic relationship, allowing the patient to verbalize fears and concerns.
- Use active listening skills to identify and validate verbal and nonverbal messages revealing anxiety and fear.
- Use touch, as appropriate, to demonstrate genuine empathy and caring.
- Be prepared to respond to common patient questions about surgery, including:
  - Will I lose control of body functions while I'm having surgery?
  - How long will I be in the operating room and PACU?
  - Where will my family be?

- Will I have pain when I wake up?
- Will the anesthetic make me sick?
- Will I need a blood transfusion?
- How long will it be before I can eat?
- What kind of scar will I have?
- When will I be able to be sexually active?
- When can I go back to work?

Preparing the Patient Psychologically Through Communicating

Surgery is almost always viewed as a life crisis and evokes anxiety and fear. Anxiety can be reduced and recovery facilitated by nursing actions that focus on therapeutic communication and patient and family teaching. Each patient is a unique person and responds to the surgical experience in a unique way. One note of caution: Avoid false reassurance. In an attempt to allay anxiety and fear, the nurse may be tempted to reassure patients that they will be fine. Such a response denies patients' emotional needs, shuts off therapeutic communications and trust, and may not be true.

The nurse uses therapeutic communication skills and techniques, as described in Chapter 8, to establish a supportive and trusting nurse–patient relationship and to facilitate psychological safety and security. Nursing interventions to meet the psychological needs of the surgical patient through communication are outlined in Box 31-2 on page 1052.

Preparing the Patient Psychologically Through Teaching

Teaching about postoperative activities, a nursing responsibility, is implemented in the preoperative phase. Patients and families need to know about surgical events and sensations, how to manage pain, and how to perform the physical activities necessary to decrease the risk for postoperative complications and facilitate recovery. The teaching–learning process (see Chapter 9) is individualized to meet universal and individual patient needs. The success of preoperative teaching varies with the timing of the teaching, the patient and their support systems, the type of surgery, and group versus individual sessions. Preoperative teaching has proven beneficial in decreasing postoperative complications and length of stay, as well as positively influencing recovery. Patients who are well prepared with detailed preoperative instruction deal more effectively with their surgery and are better prepared to manage their pain and engage in appropriate self-care activities.

The timing of teaching is a significant consideration: Teaching too far in advance of surgery or when the patient is anxious is less effective. In today's health care system, patients often enter the hospital the day of surgery and teaching must be adapted to this schedule. Many institutions provide teaching sessions before admission to prepare the patient for surgery. Whether done before or after admission, a preoperative teaching checklist gives nurses organized, comprehensive guidelines for instruction. Box 31-3 provides a sample of preoperative teaching with associated surgical events.

Box 31-3 Sample Preoperative Teaching: Activities and Events for In-Hospital Surgery

Preoperative Phase

- Exercises and physical activities
  - Deep-breathing exercises
  - Coughing
  - Incentive spirometry
  - Turning
  - Leg exercises
  - Early mobility
- Pain management
  - Meaning of PRN orders for medications
  - Multimodal pain medication options
  - Timing for best effect of medications
  - Splinting incision
  - Nonpharmacologic pain management options
- Visit by anesthesiologist or CRNA
- Physical preparation
  - NPO
  - Medications the night before/day of surgery

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Preoperative checklist (review items)
- Visitors and waiting room
- Transported to operating room

Intraoperative Phase

- Holding area
  - Skin preparation
  - Intravenous lines and fluids
- Medications
- Operating room
  - Operating room bed
  - Lights and common equipment (e.g., cardiac monitor, pulse oximeter, warming device)
  - Safety belt and other positing devices/equipment
  - Sensations
  - Health care team roles

Postoperative Phase

- Postanesthesia care unit
  - Frequent vital signs, assessments (e.g., orientation, movement of extremities, strength of grasp)
  - Dressings/drains/tubes/catheters
  - Intravenous lines
  - Pain medications/comfort measures
  - Family notification
  - Sensations
  - Airway/oxygen therapy/pulse oximetry
  - Health care team roles
- Transfer to unit
  - Frequent vital signs
  - Sensations
  - Pain medications/nonpharmacologic strategies
  - NPO, diet progression
  - Exercises
  - Early ambulation
- Visitation policies

TEACHING ABOUT SURGICAL EVENTS AND SENSATIONS

When surgery is scheduled, explain to patients and their families how long the surgery and postanesthesia care will last, as well as what will be done before, during, and after surgery (e.g., procedures, medications, equipment). If the surgery is elective, an actual or computerized tour of the operating suite, or a video of the preoperative journey to the OR may be helpful in reducing anxiety and fear of the unknown. This is especially helpful for children. Provide an explanation of surgical events, including a description of the various members of the health care team; where and when to report for admission; instructions for preoperative skin preparation, fasting, and bowel prep, if prescribed; instructions for taking special medications; and the importance of bringing a responsible adult to drive the patient home. Explain to patients that they may not drive themselves home or take public transportation alone if they have had any anesthesia or sedatives.

Patients also benefit from knowing what sensory alterations they may experience during the perioperative period. Although the sensations differ depending on the type of surgery, teaching should include information about dry mouth and drowsiness from preoperative medications, a sore throat from the insertion of an endotracheal tube, a gradual return of feeling and movement after spinal anesthesia, and pain from the surgical incision. It is also important to make sure that patients are aware of the coolness of the environment, firmness of the OR bed, the sounds and sights of multiple care providers wearing surgical masks, and the bright overhead lights. Assure patients that they are the most important person in the room and will be well cared for and comforted. It is likely that the patient will receive antianxiety medication, which is also an amnesic. However, this medication should not prevent the nurse from clarifying information with patients and answering their questions.

TEACHING ABOUT PAIN MANAGEMENT

Pain is a normal part of the surgical experience and a major concern for the patient and family. Evidence-based guidelines for the management of acute surgical pain have been established by several professional organizations. The

guidelines include references to: (1) individualized, developmentally appropriate patient teaching on pain management options, plans, and goals; (2) preoperative evaluation that guides postoperative pain management; (3) ongoing assessment of pain using validated assessment tools that include both subjective and objective components of assessment; (4) incorporation of multimodal anesthesia; and (5) individualized use of pharmacologic and nonpharmacologic methods of pain management (Chou et al., 2016). Continuing or unresolved pain can increase the patient's length of recovery and delay discharge. Treat unrelieved, severe postoperative pain as a serious complication of surgery, not as a normal expectation. The nurse is responsible for assessment, implementation, and evaluation of a pain management plan, and for teaching the patient preoperatively how to communicate and report pain (see Chapter 36) so that it is manageable. Keep in mind that the absence of pain (0 on a scale of 1–10) is unreasonable after surgery; the nurse works with the patient to establish a mutually agreed-upon postoperative pain goal. Introduce children and their families to an age-specific pain scale preoperatively.

Teach the patient and family that medications to relieve pain will be prescribed by the surgeon and administered by the nurse. The provider may prescribe pain medications to be given on a regular basis or on an as needed (PRN) basis. If medication is ordered PRN, there is a time restriction between doses (e.g., every 2 or 4 hours). Explain to patients that they need to ask for the medication before the pain becomes severe. If the medication does not control the pain or if the patient has unpleasant side effects (such as nausea and vomiting), a different medication can be prescribed. Current recommendations caution against routine opioid prescription postoperatively, focusing on oral opioid administration with acetaminophen and/or nonsteroidal anti-inflammatory drugs (NSAIDs) as needed, or the use of patient-controlled analgesia (PCA) when the parenteral route is necessary (Chou et al., 2016). The use of relaxation techniques (e.g., deep breathing, music, and guided imagery) enhances the effects of pain medications, as discussed in Chapter 29. Chapter 30 discusses spinal block.

Alternative methods of pain control that may be used after surgery include transcutaneous electrical nerve stimulation (TENS), pressure-controlled pain pumps filled with local anesthetics with soaker drains placed inside the incision, and PCA pumps. PCA infusion pumps allow patients to self-administer doses of pain-relieving medication within prescribed time and dose limits. Patients activate the delivery of the medication by pressing a button on a cord connected to the pump or a button directly on the pump. Teach the patient how to use these methods of pain control before surgery and monitor their effectiveness after surgery. A discussion of TENS and information about nursing interventions when using PCA are in Chapter 35.

TEACHING ABOUT PHYSICAL ACTIVITIES

The most common causes of postoperative complications are alterations in cardiovascular and respiratory function, including atelectasis, pneumonia, thrombophlebitis, DVT, and thromboembolism. Physical activities to reduce the risk for these complications include deep breathing, coughing, incentive spirometry, leg exercises, turning in bed, and early ambulation. These and other activities that will be required postoperatively are taught in the preoperative period. The patient should be able to state the purpose and demonstrate the activities before going to surgery. This section gives the rationale for the activities; postoperative complications are discussed later in the chapter.

Deep Breathing

During surgery, the cough reflex is suppressed, mucus accumulates in the tracheobronchial passageways, and the lungs do not ventilate fully. After surgery, respirations often are less effective as a result of the anesthesia, pain medications, and decreased voluntary respiratory effort because of incisional or other pain. Patients who have thoracic or high abdominal incisions are especially prone to shallow breathing because of incisional pain with deeper respirations. As a result, alveoli do not inflate or may collapse and secretions are retained, increasing the risk for atelectasis and respiratory infection. Deep-breathing exercises hyperventilate the alveoli and prevent them from collapsing again, improve lung expansion and volume, help to expel anesthetic gases and mucus, and facilitate oxygenation of tissues. See Guidelines for Nursing Care 31-1 for how to teach the patient deep-breathing techniques.

► Guidelines for Nursing Care 31-1

Teaching Deep-Breathing Techniques

- Place the patient in semi-Fowler's position, with the neck and shoulders supported.
- Ask the patient to place the hands over the rib cage, so that the patient can feel the chest rise as the lungs expand.
- Ask the patient to:
  - Exhale gently and completely.
  - Inhale through the nose gently and completely.
  - Hold the breath for 3 to 5 seconds and mentally count "one, one thousand, two, one thousand," and so forth.
  - Exhale as completely as possible through the mouth with lips pursed (as if whistling).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Repeat three times.
- This exercise should be done every 1 to 2 hours while the patient is awake for the first 24 hours after surgery and as necessary thereafter, depending on risk factors and pulmonary status.

Coughing

Coughing helps remove retained mucus from the respiratory tract and usually is taught in conjunction with deep breathing—although it is recommended to write out the phrase, you may see nurses use the shorthand CDB (*cough and deep breathe*) in narrative notes. Coughing is especially important in patients with an increased risk for respiratory complications. Because coughing is often painful, teach the patient how to splint the incision (i.e., support the incision with a pillow or folded bath blanket) and to use the time after pain medication has been administered to their best advantage. See Guidelines for Nursing Care 31-2 on how to teach the patient how to cough effectively.

Incentive Spirometry

An incentive spirometer is often prescribed for patients having surgery. The proper technique for using it should be practiced preoperatively and reinforced by nurses and other members of the patient care team, including respiratory therapists. This device helps to increase lung volume, promote inflation of alveoli, and facilitate venous return. A gauge on the incentive spirometry device allows patients to measure their progress and provides immediate positive reinforcement for the breathing efforts. See Chapter 40 for more information.

Leg Exercises

During surgery, venous blood return from the legs slows. In addition, some surgical positions, such as having the legs elevated in the lithotomy position (see illustration in Box 27-2 on page 1052), decrease venous return. With circulatory stasis in the legs, thrombophlebitis, DVT, and the risk for emboli are potential complications. Leg exercises increase venous return through flexion and contraction of the quadriceps and gastrocnemius muscles. Leg exercises must be individualized to patient needs, physical condition, physician preference, and facility protocol. Figure 31-2 highlights how to teach the patient to perform leg exercises that engage the ankles and feet.

Guidelines for Nursing Care 31-2

Effective Coughing

- Place the patient in a semi-Fowler's position, leaning forward.
- Provide a pillow or folded bath blanket to use in splinting the incision.
- Ask the patient to:
  - Inhale and exhale deeply and slowly through the nose three times.
  - Take a deep breath and hold it for 3 seconds.
  - "Hack" out for three short breaths.
  - With mouth open, take a quick breath.
  - Cough deeply once or twice.
  - Take another deep breath.
  - Repeat the exercise every 2 hours while awake.

Encouraging the patient to "hack" out three short coughs after holding their breath.

Turning in Bed

Turning in bed improves venous return, respiratory function, and intestinal peristalsis, while preventing the unrelieved skin pressure that would occur if the patient were to remain in only one position. Although turning in bed sounds like

a simple procedure, incisional pain makes it difficult, underscoring the need for practicing it before surgery. To turn in bed, patients should raise one knee, reach across to grasp the side rail on the side toward which they are turning, and roll over while pushing with the bent leg and pulling on the side rail. A small pillow is useful for splinting the incision while turning. The patient should turn and change positions in bed every 2 hours when awake.

Early Ambulation

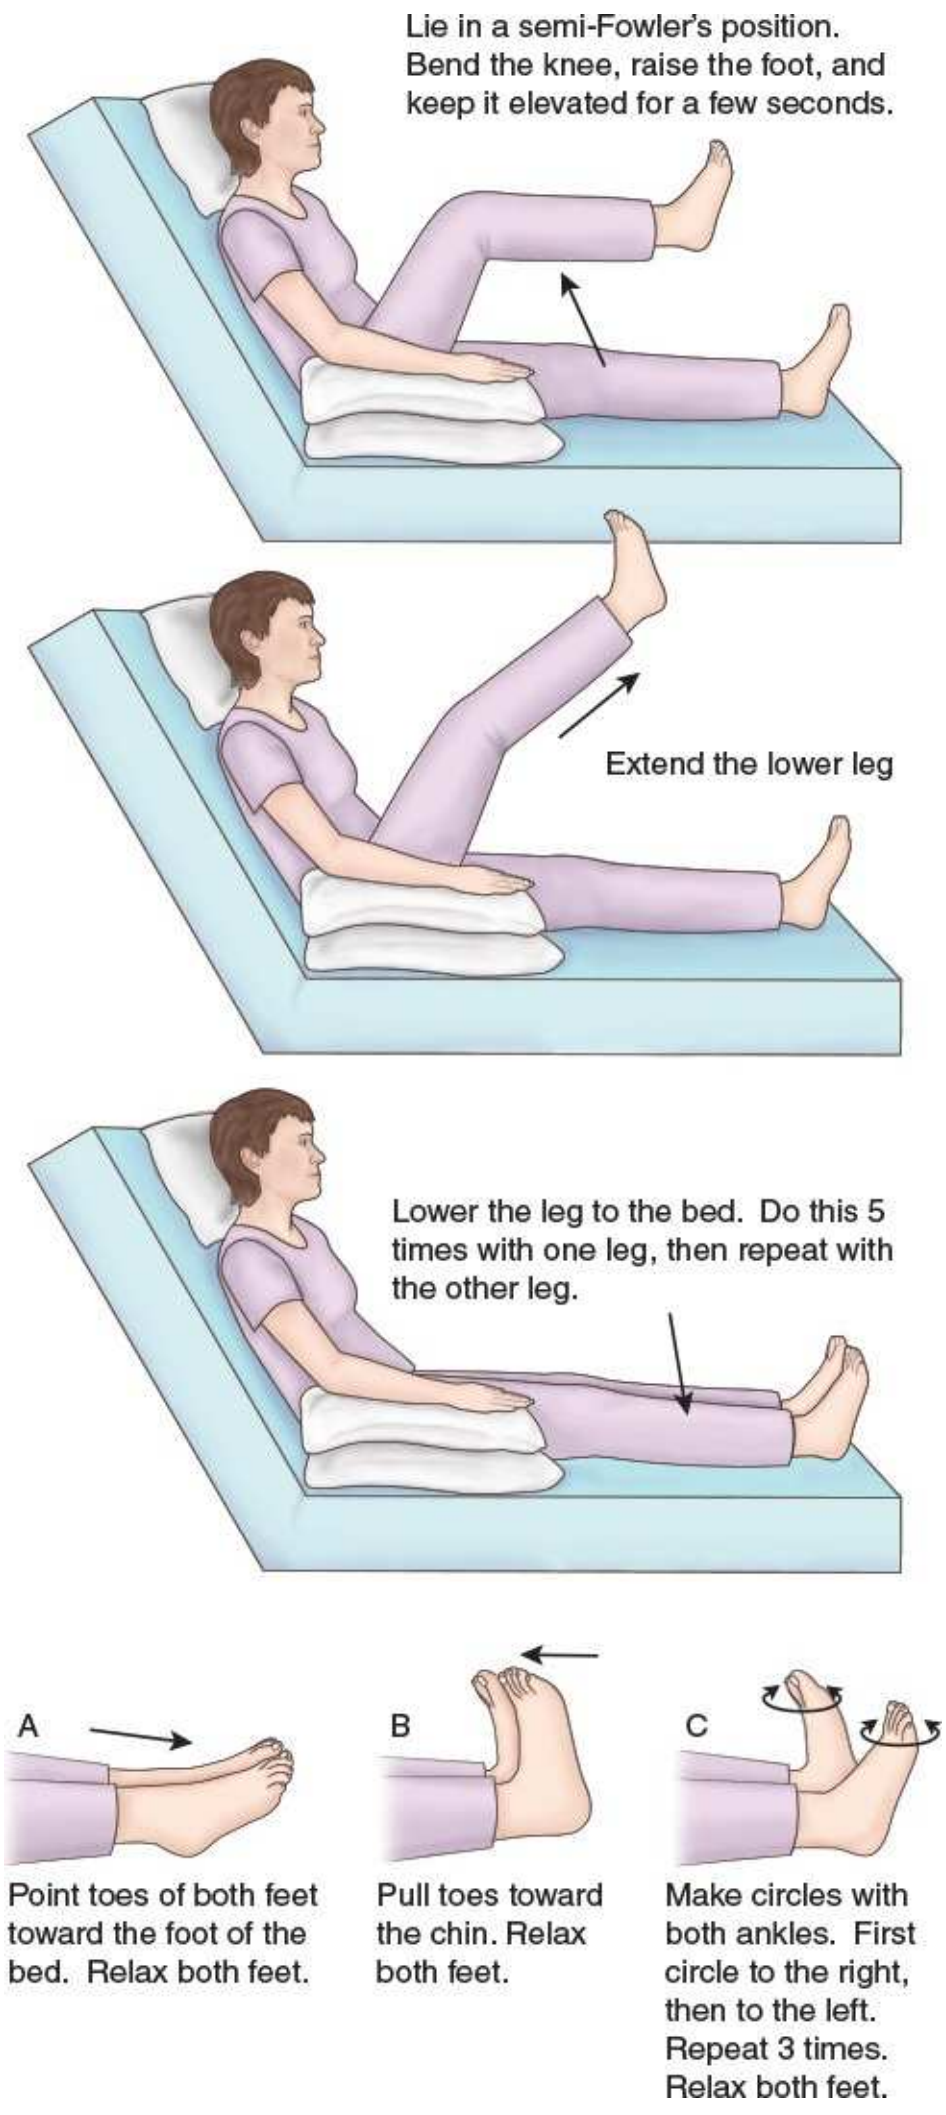

FIGURE 31-2. Leg exercises to increase venous return.

Although related to leg exercises and turning in bed, early ambulation has positive effects on the respiratory, cardiovascular, integumentary, musculoskeletal, gastrointestinal, and renal systems. Discussing the benefits during the preoperative period helps patients fully engage in this activity (as appropriate) postoperatively despite expected pain and discomfort.

Preparing the Patient Physically

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

The physical preparation of the patient for surgery varies, depending on the patient's physical status and special needs, type of surgery, and the health care provider's orders. Certain nursing interventions are appropriate for all surgical patients in the areas of hygiene and skin preparation, elimination, nutrition and fluids, and rest and sleep. The nurse is also responsible for the preparation and safety of the patient on the day of surgery.

HYGIENE AND SKIN PREPARATION

Intact skin is the body's first line of defense against microorganisms, and the surgical incision provides a potential entry for infection. Therefore, the skin is prepared to minimize skin contamination and decrease the risk for postoperative surgical site infection.

The skin is cleaned at the operative site with an antibacterial soap or solution to remove bacteria. The patient can do this while taking a bath or shower the day of or night before surgery. The specific choice of soap or antiseptic product depends on the patient, the procedure, and manufacturer recommendations (AORN, 2020; Cowperthwaite & Holm, 2015), but there is a renewed emphasis on protocols that include providing clear verbal and written instructions for patients, with electronic reminders sent as appropriate (Stanton, 2021). Although the evidence is mixed in the literature, many facilities have specific surgical bundles or protocols that include preoperative showers or baths using soap, followed by an antiseptic wash using some combination of FDA-approved iodine-, alcohol-, and/or chlorhexidine gluconate (CHG)-based products (AORN, 2020). Ideally, a tinted antiseptic that is visible on the skin should be used (Stanton, 2021). For example, the nurse may need to cleanse children and adult inpatients preoperatively with microfiber cloths impregnated with 2% CHG antimicrobial skin antiseptic. This skin antiseptic eliminates skin microorganisms and leaves an antimicrobial film on their skin. Shampooing the hair and cleaning the fingernails also help to reduce the number of organisms present on the body.

Leave hair at the surgical site in place if possible. Removal of hair at the surgical site depends on the amount of hair, the location of the incision, and the type of surgical procedure being performed. If ordered, this may be done on the unit or in the surgical suite immediately before the operation, usually in the surgical holding area. If hair must be removed, AORN (2020) recommends removing only the hair that will interfere with the surgical procedure using hair clippers as close to the time of surgery as possible. Document the condition of the skin, method of hair removal, and skin preparation site and agent. Instruct the patient not to shave the area of the surgical site prior to surgery unless so directed by the health care provider.

ELIMINATION

Emptying the bowel of feces is no longer a routine procedure before surgery. The nurse uses the preoperative assessment to determine the need for a prescription to facilitate bowel elimination. If the patient has not had a bowel movement for several days or has had preoperative barium diagnostic tests, an enema helps prevent postoperative constipation.

If the patient is scheduled for surgery of the lower gastrointestinal tract, a bowel prep and cleansing enema may be prescribed. Peristalsis does not return for 24 to 48 hours after the bowel is handled, so preoperative cleansing helps to decrease postoperative constipation. An empty bowel also prevents contamination of the surgical area during surgery.

Insertion of an indwelling urinary catheter may be prescribed before surgery, especially in patients having pelvic surgery, to prevent bladder distention or accidental injury. If an indwelling catheter is not in place, instruct the patient to void immediately before receiving preoperative medications to ensure an empty bladder during surgery.

NUTRITION AND FLUIDS

Patients need to be well-nourished and hydrated before surgery to counterbalance fluid, blood, and electrolyte loss during surgery; to facilitate anesthesia delivery; to counter the surgical stress response; and to promote tissue healing after surgery. The surgical stress response involves endocrine (hormonal), hematologic, metabolic, and immune changes that are triggered to compensate for intravascular volume depletion, cardiac output and oxygen consumption changes, and energy expenditures associated with the stress of surgery and the immune response (Gillis & Wischmeyer, 2019). Integration of a nutrition assessment, ideally performed by a registered dietician using a validated instrument, provides baseline information that informs preoperative and postoperative decisions regarding supplemental nutrition, fluids, or electrolytes (see Chapter 41). A patient who is undernourished or malnourished may require nutritional intervention to shore up their physiological reserve prior to surgery to increase their capacity to respond to surgical stress. This nutritional support should continue postoperatively (Gillis & Wischmayer, 2019). In emergencies, IV fluid and blood products are administered as needed to the patient prior to surgery.

Although maintaining an NPO status for at least 8 hours prior to surgery was formerly the standard, the American Society of Anesthesiologists (2017) revised the practice guidelines for preoperative fasting. Current practice guidelines allow patients to drink clear liquids up to 2 hours before surgery. If clear liquids are allowed by the health care provider, the patient should be taught that clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee. These liquids do not include any alcohol. Patients, especially children, may be less anxious, better hydrated, and experience fewer headaches and nausea after surgery if permitted selected fluids. Infants may receive breast milk 4 hours before surgery and may receive infant formula 6 hours before surgery (Nelson

et al., 2018). Light meals such as tea and toast may be consumed up to 6 hours before surgery; regular meals should be finished 8 hours before surgery.

The nurse explains the reason for being NPO to the patient and, at the appropriate time, removes all food and fluids from the bedside, and indicates NPO status per the unit routine (sign, white board, etc.) so that all health team members and visitors know about the restriction. If the patient eats or drinks, notify the health care provider at once; the procedure may have to be delayed or cancelled.

REST AND SLEEP

Rest and sleep are important in reducing the stress before surgery and for healing and recovery after surgery. The nurse can facilitate rest and sleep in the immediate preoperative period by meeting psychological needs, focusing on just-in-time teaching, providing a quiet environment, encouraging individualized relaxation or comfort measures, or administering the prescribed sedative medication for hospitalized surgical patients.

Preparing the Patient on the Day of Surgery

A preoperative checklist is often used to outline the nurse's responsibilities on the day of surgery; these activities must be completed and documented before the patient is transported to surgery. Some of these activities have already been described (e.g., NPO, preoperative teaching, informed consent, skin preparation, screening tests, bladder elimination).

Preoperative medications that might be prescribed are as follows:

- A benzodiazepine, such as midazolam to alleviate anxiety, produce sedation, and promote amnesia (U.S. National Library of Medicine, 2020)
- A synthetic short-acting opioid, such as alfentanil, to facilitate patient sedation and relaxation and to decrease the amount of anesthetic agent needed (National Center for Biotechnology Information, 2020)
- A highly selective α2-adrenergic receptor agonist, such as dexmedetomidine, to reduce anesthesia requirements and pain (Obara, 2018)

Guidelines for Nursing Care 31-3 provides further information about preoperative interventions the day of surgery for a hospitalized patient.

Evaluating

Evaluating the care plan for the preoperative phase is based on the expected outcomes. The plan is effective if the patient is physically and emotionally prepared for surgery, verbalizes expected events and sensations of the perioperative period, and demonstrates postoperative exercises and activities.

Guidelines for Nursing Care 31-3

Providing Preoperative Patient Care: Hospitalized Patient (Day of Surgery)

- Check that preoperative consent forms are signed and dated, witnessed, and correct. Verify advance directives are in the medical record (as applicable).
- Gather the needed equipment and supplies.
- Perform hand hygiene.
- **Check vital signs.** Notify the health care provider of any pertinent changes (i.e., rise or drop in blood pressure, elevated temperature, cough, symptoms of infection).
- Provide oral care. Assess for loose teeth. **Verify adherence to food and fluid restrictions before surgery.**
- Facilitate/verify bathing was completed the morning of or night before surgery. **Complete any skin antiseptic preparation per surgical protocol or bundle.**
- Instruct the patient to remove all personal clothing, including underwear, and put on a hospital gown.
- Ask patient to remove cosmetics, jewelry including body piercings, nail polish, and prostheses (e.g., contact lenses, false eyelashes, dentures). Some facilities allow a wedding band to be left in place, depending on the type of surgery, provided it is secured to the finger with tape.
- If possible, give valuables to a family member or place valuables in an appropriate area, such as the hospital safe.
- **Have the patient empty their bladder before surgery.**
- Attend to any special preoperative orders, such as starting an IV line.
- Complete the preoperative checklist and the record of the patient's preoperative preparation.
- **Administer preoperative medication as prescribed by the surgeon/anesthesia provider.**
- Raise the side rails of the bed; place the bed in the lowest position. Instruct the patient to remain in the bed or on the stretcher. If necessary, a safety belt may be used.
- Help move the patient from the bed to the transport stretcher if necessary. Reconfirm patient identification and ensure that all preoperative events and measures are documented.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Tell the family of the patient where the patient will be taken after surgery and the location of the waiting area where the surgeon will come to explain the outcome of the surgery.
- After the patient leaves for the OR, prepare the room and make a postoperative bed for the patient. Anticipate any necessary equipment based on the type of surgery and the patient's history.

NURSING PROCESS FOR INTRAOPERATIVE CARE

The intraoperative phase of surgery begins with admission of the patient to the surgical area and lasts until the patient is transferred to the PACU or other recovery area. The perioperative nurse has critical responsibilities and roles in collaboratively meeting patient needs. The nursing process uses the preoperative data and plan as a basis for the intraoperative plan of care.

Assessing

The first room the patient enters when transferred to the surgical area is the preoperative holding area. Nurses in surgical scrub attire identify the surgical patient, assess the patient's emotional and physical status, and verify the information on the preoperative checklist, including assessment data, lab reports, and consents for surgery and blood transfusion. They may also carry out required immediate preoperative care, including performing skin preparation, starting IV fluids, placing intermittent pneumatic compression devices (IPCDs) to prevent DVT, determining pain level, reassuring patient and family, providing comfort, and giving preoperative medications. The nurse also assesses the patient's response to the procedures and explains the events of surgery. Review Figure 31-3 on page 1058, a surgical checklist from AORN that seamlessly incorporates the standards and requirements from Joint Commission and the World Health Organization (WHO; AORN, 2020).

When the OR is ready, the patient is transported to the OR. Once the patient transfers from the stretcher to the OR bed, the patient is identified again with the operative team using at least two identifiers (such as name, birth date). The patient is then anesthetized, positioned, prepped, and draped. The perioperative nurse assesses the patient and reviews preoperative data, paying particular attention to factors that increase surgical risk. To maintain patient safety, the nurse also assesses the patient during positioning, and monitors supplies used.

Diagnosing Actual or Potential Health Problems and Needs

Patient problems in the intraoperative period may occur as a result of the position of the patient, the effects of the anesthesia, equipment used, disruption of tissues during the operative or invasive procedure, and the incision. Examples of patient problems or needs with related etiology and signs and symptoms can be found in the box titled Examples of Actual or Potential Health Problems and Needs: Intraoperative Patient on page 1058.

Outcome Identification and Planning

The planning phase of the nursing process focuses on identifying interventions most effective for preventing complications, anticipating patient problems, and ensuring patient safety. Some expected outcomes are that the patient will:

- Remain free of neuromuscular injury
- Remain free from wrong-site, wrong-side, wrong-patient surgical procedure

COMPREHENSIVE SURGICAL CHECKLIST

Source: Association of periOperative Registered Nurses (AORN). (2020). Guidelines for perioperative practice. AORN, Inc. https://www.aorn.org/guidelineshttps://www.aorn.org/guidelines; International Council of Nurses (ICN). (2019). Nursing diagnosis and outcome statements. https://www.icn.ch/sites/default/files/inline-files/ICNP2019-DC.pdf; Wolters Kluwer. (2022). *Problem-based care plans*. In Lippincott Advisor. Wolters Kluwer. https://advisor.lww.com/lna/home.do

- Maintain fluid and electrolyte balance
- Maintain skin integrity (other than the incision)
- Have symmetric breathing patterns
- Be free of injury from burns, retained surgical items (inaccurate count of sharps, instruments, and soft goods such as surgical sponges used during the procedure), and medication errors
- Remain free from surgical site infection
- Maintain normothermia

Implementing

During surgery, nurses function as scrub nurses and perioperative registered nurse (RN) circulators, in an expanded role as registered nurse first assistants (RNFAs), or as advanced practice registered nurses (APRNs), including CRNAs.

The scrub nurse is a member of the sterile team who maintains sterile technique while draping and handling instruments and supplies. The perioperative RN circulator, assigned to a patient for the duration of the procedure, serves as a patient advocate. The RN circulator coordinates the plan of care, establishes collaborative relationships while supervising and evaluating the surgical team, facilitates transitions of care, and provides direction and intervention in emergency situations (AORN, 2019). The perioperative RN circulator is ultimately responsible for the nursing-specific patient outcomes of the operative or other invasive procedure (AORN, 2020) and facilitates the following: appropriate transfer and positioning of the patient; surgical site/skin antiseptic preparation; verifying and providing additional supplies or medications; anticipating needs of the surgical team to facilitate the procedure; maintaining environmental safety; and counting the number of instruments, sharp items such as needles, and soft goods such as sponges used during the surgery to prevent the accidental loss of an item in the surgical site. The RNFA actively assists the surgeon by providing exposure of the operative area, hemostasis (by using surgical clamps or other medical devices on bleeding tissue), and wound closure. The APRN coordinates care activities; collaborates with physicians and nurses in all phases of perioperative and postanesthesia care; and integrates case management, critical paths, and research into care of the surgical patient. A CRNA may be directly involved in administering anesthesia and anesthesia-related care. Additional educational preparation is required for the roles of the RNFA and the APRN.

Error Prevention

Despite current safeguards and processes, **never events** occur in the surgical setting. These never events are considered sentinel events by the Joint Commission, and the Centers for Medicare and Medicaid Services (CMS) does not reimburse hospitals for any expenses incurred as a result of a preventable patient injury. Public reporting of these errors improves the quality of care, and hospitals are under increased pressure to correct the problems that contribute to these events (Agency for Healthcare Research and Quality [AHRQ], 2019). Examples of these errors include leaving a foreign object in the patient's body, performing the wrong surgery, or operating on the incorrect body site (AHRQ, 2019). The Joint Commission (2020), an independent accrediting facility for health care organizations and facilities, has established the Universal Protocol to prevent wrong-site, wrong-procedure, and wrong-person surgery. The universal protocol has three components:

1. Preoperative patient identification verification process
2. Marking the operative site
3. Final verification just prior to beginning the procedure, referred to as the **time-out**

The time-out occurs immediately before starting the surgical procedure and is initiated by a designated member of the team. The surgeon, the anesthesia provider, the RN circulator, the OR technician, and any other active participants conduct the time-out assessment and ensure that there are no questions or concerns. During the time-out, all members of the surgical team must agree on the identity of the patient, the correct surgical site, and the procedure that will be performed. The completion of the time-out is documented appropriately. To further minimize patient risk in the dynamic perioperative setting and promote safe, quality care, AORN (2019) believes that a minimum of one perioperative RN circulator should be dedicated to each patient for the duration of that patient's intraoperative experience.

Positioning

Preoperative assessment findings guide the nurse in knowing extremity limitations and other functional needs to individualize patient care. The equipment in the room should be prepared prior to the procedure based on the planned

procedure, the surgeon's preferences, and the status of the patient (AORN, 2020). The patient is placed in a specific operative position after anesthesia has produced loss of consciousness and reflexes. Using proper body mechanics and following the directions provided by the manufacturer for any equipment, the nurse works with the entire surgical team to coordinate any required movement and maintain body alignment. The risk for skin injury is avoided by lifting with a lateral-transfer device, rather than rolling or pulling the patient into the surgical position. Rolling or pulling can cause a shearing force, in which two or more tissue layers slide on each other, stretching subcutaneous blood vessels, obstructing blood flow, and contributing to pressure injuries (AORN, 2020). Although all of the operative positions are not described here, perioperative nurses need to know the position that will be used and significant nursing considerations for that position. Two examples are the Trendelenburg position and the lithotomy position. The Trendelenburg position requires lowering the upper torso and raising the feet. It is commonly used in minimally invasive surgery of the lower abdomen or pelvis. The displacement of the abdominal viscera toward the head decreases diaphragmatic movement and respiratory exchange; pooling blood increases intracranial and intraocular pressures; and hypotension can result with return to the supine position. When possible, patients should not be kept in this position for extended periods of time, and skin should be monitored for shearing. The lithotomy position is used for gynecologic, rectal, and urologic procedures. The placement of legs in stirrups causes pooling of blood in the legs, increasing the risk of DVT. Pressure can also damage the peroneal nerve, with resultant foot drop. Patients can experience lower back strain if they are not positioned slowly and carefully (AORN, 2020). Refer to Chapter 27 for additional information regarding body positions.

Draping

Drapes are used to create and maintain a sterile field around the operative site, preventing the passage of microorganisms, particulate matter, and fluids between sterile and nonsterile areas. The only area left exposed is the incision site. In some cases, plastic adhesive drapes may be used to form a complete seal over the skin. With these drapes, skin color is visible, and the incision is made through the impermeable adhesive drape.

Documenting

Throughout surgery, the perioperative nurse documents on the intraoperative record ongoing patient assessment, item counts (soft goods, sharps, instruments), monitoring data (e.g., vital signs, urine output, blood loss, pulse oximetry results, body temperature), positioning, medications, dressings and drains, specimens, equipment used (electrosurgery unit and settings, ultrasound, video, stirrups for positioning), and responses to care. This documentation includes planning and implementation of perioperative nursing activities and evaluation of the achievement of patient outcomes.

Through the Eyes of a Student

The first time I took care of a patient with "multiple tubes," I was horrified at the thought of actually touching the patient. I hadn't really been exposed to that many critically ill patients until my last semester as a student nurse. I remember being assigned a patient in the cardiothoracic intensive care unit. The patient was a "fresh heart"—a patient who just had a coronary artery bypass graft (CABG) that morning.

I remember walking into the room and thinking, "What do I do with all of these tubes?" and then with horror thinking, "What if one of them falls out?" Needless to say, I was overwhelmed and frightened, but at the same time excited at the challenge that faced me. I asked my preceptor what each tube was for, where it was hooked up, and whether it would fall out if I touched it. They answered all my questions with patience and understanding and asked me if I wanted to handle the tubes. I looked at them as if they were unhinged but went ahead and did it. Would you believe that nothing fell out! I must admit that the experience taught me a lot, but it also got me over the fear of tubes.

I now chuckle every time I see a nursing student's face with that same look of horror I had, and I try to answer every question with the same degree of patience and understanding that my preceptor had for me.

—Lynda L. Ullmer, RN, Gaithersburg, MD

Transferring to the Postanesthesia Care Unit

After completion of the surgical procedure and emergence from anesthesia, the patient is moved carefully from the operating bed to a stretcher or bed. This is a critical time: sudden or rough handling can cause severe hypotension or potentially lethal cardiac or respiratory arrest. The patient is then transported to the PACU, and the OR nurse provides a hand-off report to the PACU nurse containing relevant preoperative and intraoperative assessments and interventions. The primary objective of the hand-off report from OR nurse to PACU nurse is to provide accurate information about the patient's care, procedure, tourniquet time, drains, medications used, presenting condition, and any important events that occurred during the procedure. It allows for communication, clarification and questions, and continuity of care.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Evaluating

Evaluation of the effectiveness of the care plan for the intraoperative phase is based on the expected outcomes. If met, the plan was effective.

POSTOPERATIVE NURSING CARE

The postoperative phase can be divided into two stages—immediate care (usually provided in the PACU in both in-hospital and outpatient/same-day surgery centers) and ongoing postoperative care (lasting from return to the unit through convalescence). Nursing assessments and interventions are consistent with those in the preoperative and intraoperative phases and are carried out to maintain function, promote recovery, and facilitate coping with alterations in structure or function. (See the accompanying Through the Eyes of a Student.) Assessments and nursing interventions are combined in discussing immediate postoperative care; the phases of the nursing process are used to describe ongoing postoperative care.

Immediate Postoperative Assessment and Care

Care in the PACU involves assessing the postoperative patient, with an emphasis on preventing complications from anesthesia and/or the surgery. Assessments are continuous, using preoperative and intraoperative data as the basis for comparison. The assessments made in the PACU include respiratory status (airway, pulse oximetry), cardiovascular status (blood pressure), temperature, central nervous system status (level of alertness, movement, shivering), fluid status, wound status, gastrointestinal status (nausea and vomiting), and general condition. These assessments initially are made every 10 to 15 minutes.

The average PACU stay is about 1 hour, but it will vary depending on the type of surgery, length of anesthesia, and patient response. Outpatient/same-day surgical patients return home after full recovery in the PACU or phase 2 recovery. The critical role functions of the PACU nurse include vigilant monitoring during emergence from anesthesia and the first hours after surgery, managing pain, maintaining fluid and electrolyte balance, stabilization of physiologic parameters (such as heart and respiratory rates), and preparation for the next level of care.

Mr. Benjamin, the older adult who has had a total hip replacement, will require frequent assessments during his stay in the PACU, specifically vital signs, cardiovascular status, respiratory status, IV therapy, wound status, and gastrointestinal status. If he had spinal anesthesia, neurologic assessments would be done every 15 minutes.

Respiratory Status

The nurse assesses respiratory function by monitoring respiratory rate, rhythm, and depth; auscultating breath sounds; noting the oxygen saturation level and PCO_2 levels; assessing skin color; and observing cardiovascular and mental status. During a surgical procedure with general anesthesia, an endotracheal tube may be inserted to administer the anesthetic gases and maintain patent air passages. This artificial airway is not removed until the laryngeal and pharyngeal reflexes return, allowing the patient to control the tongue, cough, and swallow. If newer short-acting anesthetic agents are used, the endotracheal tube is usually removed in the OR. The nurse assesses the patient's airway for patency, administers oxygen, and initiates pulse oximetry. Ineffective respiratory function is indicated by restlessness and anxiety; unequal chest expansion with use of accessory muscles; shallow, noisy respirations; cyanosis; and tachycardia.

Respiratory obstruction is the most common PACU emergency. It may occur as a result of secretion accumulation, obstruction by the tongue, laryngospasm (a sudden, violent contraction of the vocal cords and laryngeal closure), or laryngeal edema. Respiratory obstruction is diagnosed when there is ineffective respiratory function accompanied by wheezing or crowing sounds with respiratory effort. In the case of respiratory distress due to laryngospasm, call for help—early recognition and intervention is key. The recommended initial step involves maneuvers to open the airway: (1) firm pressure behind the angles of the jaw on both sides (Fink, 1956); or (2) firm upward pressure at the "laryngospasm notch bounded anteriorly by the condyle of the mandible, posteriorly by the mastoid process, and superiorly by the base of the skull" (Larson, 1998, p. 1293). Opening the airway is followed by the administration of oxygen, management of secretions, and, if respiratory distress is still unresolved, the administration of sedatives/paralytics and consideration of reintubation (Sibert et al., 2020). General nursing interventions, including positioning to promote drainage of secretions,

administering humidified oxygen, encouraging the patient to take deep breaths, and suctioning, may be used to maintain a patent airway and tissue oxygenation.

Cardiovascular Status

Assess cardiovascular function by taking vital signs, monitoring electrocardiogram rate and rhythm, and observing skin color and condition. Compare blood pressure findings with baseline data from the preoperative period. Transient hypertension can occur as a result of anesthetic effects, respiratory insufficiency, the surgical procedure, or the excitement phase of recovery from anesthesia.

Hypotension may be the result of varied factors, including preoperative medications, anesthetic agents, position changes, blood loss, respiratory alterations, and peripheral blood pooling. Oxygen administration, deep breathing, leg exercises, verbal stimulation (to help expel anesthetic gases and facilitate increasing level of consciousness), and maintaining or increasing IV fluid administration rates can raise low blood pressure.

Patients are at risk for altered body temperature related to the surgical procedure, its length, anesthetic agents, a cool surgical environment, age, and use of cool irrigating or infusion fluids. Inadvertent **hypothermia** (temperature below 36°C [96.8°F]) can lead to complications of poor wound healing, hemodynamic stress, cardiac disturbances, coagulopathy, delayed emergence from anesthesia, and shivering with its associated discomfort (AORN, 2020). Routinely measure the patient's core body temperature using an invasive/noninvasive device, or estimate core body temperature with peripheral measurement (oral/axilla/rectum) using a thermometer or probe. Note that current guidelines do not recommend infrared methods, such as tympanic membrane measurement, for the perioperative patient (AORN, 2020). If the patient is hypothermic, warmed blankets placed on the patient's body and forced warm-air devices are used for rewarming.

Assess all pulses for bilateral equality, rhythm, rate, and character. Of special significance are assessments of abnormal function—an irregular rhythm, absence of pulses, or tachycardia. Carefully evaluate for tachycardia, an early symptom of shock. Other related assessments for shock are a decreasing blood pressure, cyanosis, a cool skin temperature, and a decrease in urine output. After surgery on an extremity, closely monitor pulse checks, neurologic checks, color, temperature, and sensation.

Central Nervous System Status

The return of central nervous system function is assessed through the patient's response to stimuli and orientation. Consciousness returns in reverse order, with the usual pattern being: (1) unconsciousness, (2) response to touch and sounds, (3) drowsiness, (4) awake but not oriented, then (5) awake and oriented. Nurses in the PACU verbally reorient the patient by gently touching and calling the patient by name. If the patient had spinal anesthesia, neurologic checks are done every 15 minutes for the first hour. Differentiating alterations in level of consciousness that are expected during this phase from those that are unexpected or related to another underlying cause, such as delirium or hypoxia, requires experience and clinical judgment.

Fluid Status

Fluid imbalance may result from factors such as preoperative fluid restriction, fluid loss during surgery, wound drainage, or the surgical stress response (with retention of sodium and water). Imbalanced fluid volume (deficit or excess) is a risk for all surgical patients but is an especially important consideration in children and older adults. Monitor fluid status by assessing skin turgor, vital signs, urine output, wound drainage, and the OR's documentation of total intake and output. IV fluid administration assessments include the type of fluid or blood product infused, the rate, location of lines, condition of the IV insertion site, and the security and patency of the tubing.

Wound Status

The nurse in the PACU assesses the dressing over the incision for amount, consistency, and color of drainage, as well as for any tubes or drains and the amount and type of drainage by that route. Large amounts of bright-red drainage, combined with other abnormal physical status assessments (restlessness, pallor, cool moist skin, decreasing blood pressure, increasing pulse and respiratory rates), may indicate hemorrhage and hypovolemic shock. Report these symptoms immediately. Nurses in the PACU and throughout the postoperative period must turn patients to ensure that there is no drainage or blood pooling under the patient.

Concept Mastery Alert

If a large amount of fresh red drainage appears on a patient's dressing, the nurse should *not* remove the dressing and apply a new one. It is best to reinforce the dressing with additional bandages to reduce the possibility of hemorrhage resulting from dislodging clots that may be forming.

Pain Management

Pain is both a subjective and an objective experience. Pain management experts recommend the assessment of pain using a rating scale. The scale may be verbal (ranging from *no pain* to *worst possible pain*), numeric (with *10* on a scale

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

of 0–10 being the worst possible pain), or a FACES rating scale, ranging from a smiley face indicating no pain to a face that has frowns and tears for worst possible pain (see Chapter 36). Initial pain management, using NSAIDs and opioids, occurs in the PACU. Opioids may be delivered by PCA, allowing the patient to control the analgesic administration. Nonpharmacologic methods to decrease pain and improve comfort include positioning, verbal reassurance, and touch. These should supplement, not substitute for, pharmacologic pain relief. Preoperative determination of mutually agreed upon, realistic pain goals and identification of methods that are personally effective for the patient assist in effective implementation in the PACU.

General Condition

Other assessments and interventions are made to ensure physical and emotional comfort and safety. Constant reorientation and reassurance that the surgery is completed provide psychological comfort. Careful assessments, proper positioning, and use of side rails maintain physical safety. The patient is discharged from the PACU when their physical status and level of consciousness are considered stable. The PACU nurse should notify visitors that the patient is being transferred back to the patient's room. Use of a standardized hand-over process, tool, or checklist decreases communication breakdowns, increases the quality of information communicated, and promotes the safe transition of care (AORN, 2020).

Ongoing Postoperative Care

Ongoing postoperative care is planned to facilitate recovery from surgery and coping with alterations. The plan includes promoting physical and psychological health, preventing complications, and teaching self-care for when the patient returns home. Skill 31-2 (on pages 1074–1080) outlines initial and ongoing postoperative patient care.

NURSING PROCESS FOR ONGOING POSTOPERATIVE CARE

Assessing

For hospitalized patients, the nurse on the unit assists PACU personnel in transferring the patient and performs an initial assessment using data from the preoperative and intraoperative phases. A postoperative checklist or flow sheet may be used. The initial assessment is often combined with the implementation of postoperative health care provider's orders. See Table 31-2 for focused assessments and interventions.

After conducting the assessment, document the time of arrival and all assessment data. Facility protocol is followed for assessment routines: Common time frames are every 15 minutes until stable, changing to every 1 to 2 hours for the first 24 hours, and every 4 hours thereafter. Although protocols are used as guidelines in the immediate postoperative period, the nurse is responsible for using their clinical judgment to adjust the frequency and priorities of assessment to meet the specific needs of each patient.

Diagnosing

The nurse uses assessment data, the plan of care established before and during an operative or other invasive procedure, and input from caregivers to identify actual and potential patient problems in the postoperative phase. Examples of patient problems or needs with related etiology and signs and symptoms can be found in the box titled Examples of Actual or Potential Health Problems and Needs: Postoperative Patient.

Table 31-2 Postoperative Assessments and Interventions Upon Return to the Unit

FACTORS TO ASSESS	ASSESSMENTS AND INTERVENTIONS
Vital signs and oxygen saturation	• Obtain temperature, blood pressure, pulse, respiratory rate, and oxygen saturation. • Note, report, and document deviations from preoperative and PACU data as well as symptoms of complications.
Color and temperature of skin	• Inspect skin for color (pallor, cyanosis), temperature, and moisture (diaphoresis).
Level of consciousness	• Verify type of anesthesia and any reversal agents administered. • Assess and reorient (as needed) to person, place, and time. • Assess reaction to stimuli and ability to move all four extremities.
Intravenous fluids	• Verify estimated blood loss in the OR. • Check infusion site(s).

	• Verify type and amount of solution, flow rate, security, and patency of tubing.
Surgical site	• Verify surgical procedure, location, approach, and any positioning requirements. • Assess dressing and dependent areas for drainage (color, amount, consistency). • Secure drains and tubes: be sure they are intact, patent, and properly connected to drainage systems.
Other tubes	• Assess indwelling urinary catheter, gastrointestinal suction, and other tubes for drainage, patency, and amount of output. • Ensure that dependent drainage bags are hanging properly and suction drainage is attached and functioning. • If oxygen is prescribed, ensure placement of prescribed application and flow rate.
Comfort	• Verify orders for pain medications including medication(s), dose, route, and frequency. • Assess pain (location, duration, intensity) and determine whether analgesics were given in the PACU. • Assess for nausea and vomiting. • Cover the patient with a blanket. • Reorient to the room as necessary. • Allow visitors to remain with the patient after the initial assessment is completed.
Position and safety	• Place the patient in an ordered position or, if the patient is not fully conscious, place in the side-lying position. • Elevate the side rails and place the bed in locked and low position. • Perform a focused or brief head-to-toe assessment to establish a baseline.

Examples of Actual or Potential Health Problems and Needs

POSTOPERATIVE PATIENT

Actual or Potential Health Problem or Need	Possible Etiologic Factors	Potential Signs and Symptoms
Acute Pain	• Surgical incision • Required surgical positioning • Required movement to prevent postoperative complications	• Change in physiologic parameters (pulse, respirations, blood pressure) • Self-report or evidence of pain characteristics using a standardized pain instrument • Instinctive, frequent repositioning or guarding • Reports of tissue, joint, neurologic discomfort • Hesitation or refusal to ambulate or engage in coughing and deep breathing exercises
Surgical Site Infection Risk	• Patient-specific factors—comorbidities, nutritional state, compensatory mechanisms, immune response • Contamination of sterile field during operative or invasive procedure	—

Nursing Advocacy in Action

PATIENT SCENARIO

Alex is a 28-year-old male admitted to the surgical intensive care unit after undergoing a partial gastric bypass surgical procedure. He originally weighed 700 lb but lost 100 lb prior to being approved for the surgery. Patients undergoing bariatric surgery, like Alex, are usually admitted to the intensive care unit for airway management, and to ensure strict adherence to fluid intake restrictions needed to maintain the integrity of the suture line. You are assigned to care for Alex. The nurse giving the report says the following:

- "Alex is noncompliant with the fluid intake restrictions. He tries to sneak water. I don't know why we have to care for patients who are not willing to follow the medical treatment plan that they agreed to before surgery."
- "He should be repositioned hourly but since he's not motivated to participate with his ADLs, especially bathing and turning in bed, I wouldn't worry. Why should we risk hurting ourselves when he obviously doesn't care?"
- "His mother told the charge nurse yesterday that caregivers were making comments related to his size and were not providing the same quality of care as they gave to other patients."

IMPLICATIONS FOR NURSING ADVOCACY

How will you respond if you are Alex's nurse? Talk with your classmates and experienced nurses about the questions that follow.

- If you elect to advocate for Alex, what practical steps can you take to ensure better health outcomes?
- What is reasonable to expect of a student nurse, a graduate nurse, and an experienced nurse in this situation?
- What advocacy skills are needed to effectively respond to this challenge?

Outcome Identification and Planning

The plan of care in the postoperative phase begins in the preoperative phase, when nursing activities to reduce stress and teach postoperative activities are implemented. From admission, prepare the patient and family for uneventful recovery and self-care after discharge. Individualize specific expected outcomes based on risk factors, the surgical procedure, and the patient's unique needs. Examples of desired postoperative outcomes for a patient after major surgery are as follows:

The patient will:

- Carry out leg (including foot and ankle) exercises every 2 to 4 hours
- Perform effective coughing and deep breathing exercises every hour while awake
- Engage in early ambulation
- Verbalize decreasing levels of pain that meet pre-established pain goals
- Regain and maintain a balanced intake and output
- Regain normal bowel and bladder elimination
- Exhibit a healing surgical incision
- Remain free of infection—pulmonary, surgical site, or other
- Verbalize any concerns about appearance of wound
- Verbalize and demonstrate wound self-care

Implementing

Many nursing interventions in the postoperative phase have already been discussed in this chapter or are fully discussed in other chapters. Nursing care focuses on interventions that prevent complications, promote a return to health, and facilitate coping with alterations in function and/or body image.

A wide variety of factors increase the risk of postoperative complications, including age, health habits, physical condition, medical history, psychological status, and surgical intervention (e.g., anesthesia, positioning, wound). Ongoing postoperative assessments and interventions are implemented to decrease the risk for postoperative complications. If complications occur, perform focused physical assessments, provide care and emotional support to the patient and family, and carry out prescribed treatments. See Nursing Advocacy in Action for an example of a patient who may require an advocate.

Preventing Cardiovascular Complications

Nursing interventions to prevent or monitor for cardiovascular complications are listed in Box 31-4. Specific cardiovascular complications include hemorrhage, shock, thrombophlebitis and thromboembolism, and pulmonary embolus.

HEMORRHAGE

Hemorrhage is an excessive internal or external blood loss that may lead to hypovolemic shock. Nurses throughout the postoperative period must turn patients to ensure that there is no unseen blood pooling under the patient or flank ecchymosis, indicating internal bleeding. Hemorrhage and the resulting hypovolemic shock manifest as an increase in heart rate (earliest sign of shock) and associated hypotension; restlessness, anxiety, and apprehension; cold, clammy skin and cool, mottled extremities; deep, rapid respirations; and decreased urine output. The primary priorities for the patient experiencing a hemorrhage are to stop the bleeding and replace blood volume. Nursing interventions include applying a pressure dressing to the bleeding site, calling the medical intervention/rapid response team, notifying the surgeon immediately, and being prepared to have the patient return to the OR if bleeding cannot be stopped.

SHOCK

Shock is the body's reaction to inadequate organ perfusion. In shock, there is activation of compensatory mechanisms to address the resulting hypoperfusion, metabolic changes, and activation of the inflammatory response. The type of shock most commonly seen in postoperative patients is hypovolemic shock secondary to a profound loss of blood, plasma, and fluid, which decreases the circulating blood volume. Other forms of shock (cardiogenic, circulatory/distributive [septic, neurogenic, anaphylactic], obstructive) are possible depending on the surgery and patient. With all forms of shock, interventions focus on addressing the underlying cause and managing the patient's oxygenation–ventilation, fluid and nutritional balance, and blood pressure. Early recognition and treatment is the key to survival with shock.

Box 31-4 Nursing Interventions to Prevent or Monitor Postoperative Cardiovascular Complications

- Assess and document vital signs as ordered and as the patient's status dictates, using preoperative assessments as a baseline.
- Provide covers, forced warm air, or other warming device or techniques as necessary to prevent shivering and hypothermia.
- Maintain fluid balance.
- Maintain accurate intake and output.
- Monitor rate, type, and access site of IV fluids.
- Assess skin turgor and hydration of mucous membranes.
- Monitor amount, color, and consistency of wound drainage (dressings and drains or tubes).
- Implement leg exercises and turning in bed every 2 hours.
- Assist with ambulation—ambulation usually begins the evening of surgery and increases as tolerated; blood pressure and pulse and respiratory rates are used to monitor tolerance.
- Apply and follow protocols for graduated compression stockings or pneumatic compression devices, if prescribed.
- Administer anticoagulant medications, if prescribed.
- Measure bilateral calf and thigh circumference daily.
- Assess for leg swelling, tenderness, or palpable venous cord.
- Avoid positioning that impedes venous return (e.g., do not mechanically raise the knee portion of the bed or place pillows under the knees).

Specific nursing interventions include calling for the medical intervention/rapid response team and notifying the surgeon immediately; establishing and maintaining the airway; placing the patient in a flat position with the legs elevated 30 to 45 degrees; administering oxygen; monitoring vital signs, hematocrit, and blood gas results; maintaining body warmth with covers; and administering medications. The nurse must also be prepared to assist with

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

the insertion of IV lines and administer fluids, as well as packed red blood cells or other blood components.

Concept Mastery Alert

Monitoring urine output is an important nursing intervention because adequate urine output indicates adequate tissue perfusion.

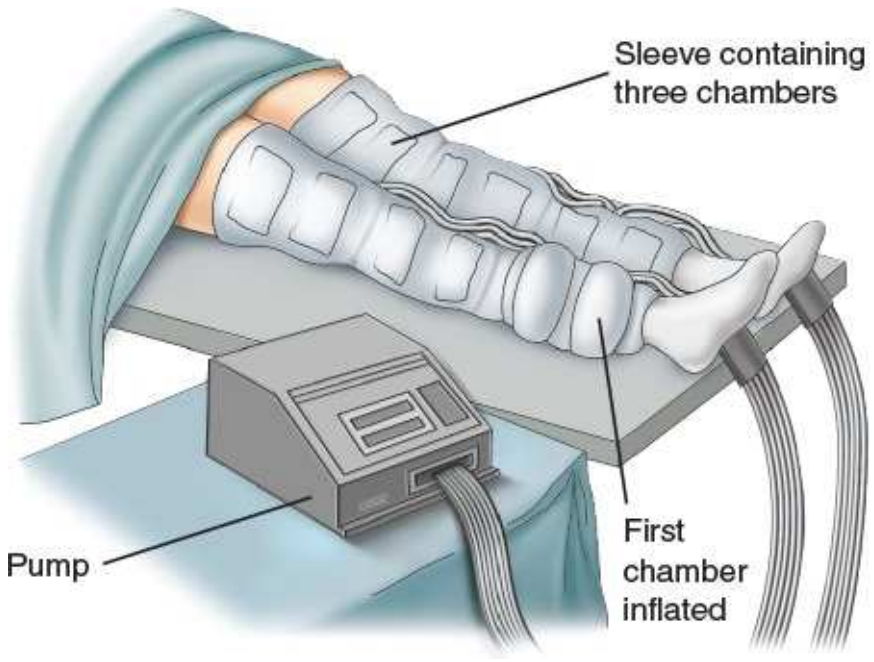
THROMBOPHLEBITIS AND THROMBOEMBOLISM

Thrombophlebitis is an inflammation of a vein associated with thrombus (blood clot) formation. Thrombophlebitis is typically superficial and, in patients without an underlying condition, is often related to IV catheters. A thrombus that forms in a deep vein, particularly in the legs of postoperative patients, is called a deep vein thrombosis (DVT). The primary goal is DVT prevention. Postoperative nursing interventions include administering medications (e.g., low–molecular-weight heparin or low-dose unfractionated heparin); correctly applying graduated compression stockings, IPCDs (Box 31-5 on page 1066), or venous foot pumps; and increasing mobility (American Association of Critical Care Nurses, 2018). Manifestations of DVT are pain and cramping in the calf or thigh of the involved extremity, redness and swelling in the affected area, elevated temperature, and an increase in the diameter of the involved extremity. This increase in extremity circumference (typically the calf) is the most significant sign of a DVT and the provider should be notified. The priority for the patient with a known DVT is preventing a clot from breaking loose and becoming a **venous thromboembolism (VTE)** that propagates (travels) to the heart, brain, or lungs (called a *pulmonary embolism*; see Preventing Respiratory Complications for more details). It is important during every shift to assess the legs for swelling and tenderness; measure bilateral calf or thigh circumference; and determine if the patient experiences any unexplained anxiety, wheezing, chest pain, or dyspnea. Patients who receive anticoagulants or other medications to prevent or treat DVT/VTE also need to be monitoring for bleeding (AORN, 2020). Instruct the patient who has a known DVT to not massage the legs.

Preventing Respiratory Complications

Nursing interventions to prevent respiratory complications include monitoring vital signs; implementing deep breathing, coughing, and incentive spirometry; turning in bed every 2 hours; ambulating; maintaining hydration; avoiding positioning that decreases ventilation; and monitoring responses to narcotic analgesics. The postoperative pulmonary care program known as I COUGH has been adopted in several institutions since its inception in 2012 (Cassidy et al., 2013). The focus of this efficacious, yet simple program is to reduce respiratory complications. To mitigate the loss of initial gains and recommit the heath care team to this effective program, the current iteration focuses on implementing standardized pulmonary practices across all surgical services, ongoing education, and addressing the underlying cultural/environmental issues that may impede implementation at a health care facility (Cassidy et al., 2020). I COUGH stands for:

- **I**ncentive spirometry
- **C**oughing/deep breathing
- **O**ral care
- **U**nderstanding (patient and staff education)
- **G**etting out of bed at least three times daily
- **H**ead of bed (HOB) elevation



Box 31-5 **Intermittent Pneumatic Compression Devices**

Pneumatic compression devices are composed of an air pump, connecting tubes, and an extremity sleeve. The sleeve may cover the entire leg or may extend from the foot to the knee. A variety of types are available; the accompanying figure provides one example. The devices apply brief pressure to the legs to enhance blood flow and venous return, thereby decreasing the risk of DVT formation after surgery. The devices may apply either intermittent or sequential pressure. Intermittent pneumatic compression devices (IPCDs) fit over the entire leg, with inflation and deflation of the sleeve covering the leg alternating from one leg to the other by a preset timer. Sequential pneumatic compression devices are designed so that pressure moves up the leg in increments. They may inflate and deflate by alternating from one leg to the other, or they may do so for both legs at once.

Nursing Care

- Explain the purpose of the device to the patient.
- Apply the device according to the manufacturer's instructions, making sure that two fingers fit between the leg and the sleeve.
- Position the tubing so that the patient can move about without interrupting the airflow.

- Remove the sleeves at least once a day for skin care and assessment.
- Assess the extremities for peripheral pulses, edema, changes in sensation, and movement on a regular schedule.
- Ensure that all chambers are inflating in proper sequence once per shift.
- Craft a plan for safe removal and storage when exiting the bed; reinforce reapplication upon return to bed

Intermittent or sequential pneumatic compression devices.

Specific respiratory complications include pulmonary embolus, atelectasis, and pneumonia.

PULMONARY EMBOLISM

A VTE is a blood clot or foreign substance that is dislodged and travels through the bloodstream until it lodges in a smaller vessel. In postoperative patients, the VTE is often part of a thrombus that breaks free from a vein wall. If the VTE lodges in the pulmonary vessels, it is called a **pulmonary embolism**. Manifestations of a pulmonary embolism include dyspnea, chest pain, cough, cyanosis, rapid respirations, tachycardia, and anxiety. This is a life-threatening condition and immediate treatment is necessary. The primary goals of care are to stabilize cardiovascular and respiratory function as well as prevent further emboli. Nursing interventions include notifying the health care provider immediately, calling the medical intervention/rapid response team, assessing vital signs frequently, administering oxygen for an oxygen saturation <90%, administering anticoagulants and other medications as prescribed (fluid and vasopressors if unstable), and preparing the patient for potential diagnostic and interventional procedures.

ATELECTASIS

Atelectasis is the incomplete expansion or collapse of alveoli with retained mucus that involves a portion of lung and results in poor gas exchange. Manifestations of atelectasis include decreased lung sounds over the affected area, dyspnea, cyanosis, crackles, restlessness, and apprehension. The primary goals of care are to ensure oxygenation of tissues, prevent further atelectasis, and expand involved lung tissues. Use of an incentive spirometer is particularly helpful in preventing atelectasis by promoting alveolar expansion. Nursing interventions include those used to prevent or monitor for respiratory complications, positioning the patient in semi-Fowler's position, administering oxygen, and administering analgesics for pain. For a sudden onset, notify the surgeon immediately and call the medical intervention/rapid response team.

PNEUMONIA

Pneumonia is an inflammation of the alveoli as the result of an infectious process or the presence of foreign material. Pneumonia may occur postoperatively as a result of aspiration, infection, depressed cough reflex, increased secretions from anesthesia, dehydration, and immobilization. Manifestations of pneumonia include fever, chills, a cough that produces rusty or purulent sputum, crackles and wheezes, dyspnea, and chest pain. The primary goals of care are to treat the underlying infection, maintain respiratory function, and prevent the spread of microorganisms. Nurses carefully monitor for sepsis which is where the infection causes a systemic inflammatory response and leads to organ dysfunction (Centers for Disease Control and Prevention [CDC], 2018). Although a slight elevation in temperature is expected after the trauma of surgery, an increase in temperature to ≥101°F or a decrease to ≤96.8°F with associated changes in white blood cell count, respiratory rate, heart rate, lactate, and/or blood glucose requires follow-up and monitoring for active infection (CDC, 2018). Nursing interventions include those used to prevent or monitor for respiratory complications, promoting full aeration of the lungs by positioning the patient in semi-Fowler's or Fowler's position, encouraging the use of incentive spirometry, promoting ambulation, administering oxygen, administering

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

medications (e.g., antibiotics, expectorants, analgesics), providing frequent oral hygiene, and ensuring rest and comfort. See the Surviving Sepsis Campaign (Society of Critical Care Medicine, n.d.) website at https://www.sccm.org/SurvivingSepsisCampaign/Home for more details on sepsis guidelines and bundles.

Box 31-6 Nursing Assessments and Interventions to Meet Postoperative Elimination Needs

Bowel Elimination

- Assess for the return of peristalsis by auscultating bowel sounds every 4 hours when the patient is awake.
- Assess abdominal distention, especially if bowel sounds are not audible or are high pitched (indicative of possible paralytic ileus, which is an absence of intestinal peristalsis).
- Assess ability to pass flatus and stool.
- Assist with movement in bed and ambulation to relieve gas pains, a common postoperative discomfort.
- Encourage food and fluid intake when ordered, especially fruit juices and high-fiber foods.
- Maintain privacy when patient is using the bedpan, commode, or bathroom.
- Administer suppositories, enemas, or medications, such as stool softeners, as prescribed.

Urinary Elimination

- Monitor patterns of intake and output.
- Assist in assuming normal position to void by using an upright position when on a bedpan and using a bedside commode or bathroom when able; assist the male patient to stand upright to void with a urinal.
- Assess for bladder distention by palpating above the symphysis pubis if the patient has not voided within 8 hours after surgery or if the patient has been voiding frequently in amounts of less than 50 mL; bladder scan PRN, notify the health care provider of abnormal assessment results.
- Maintain prescribed intravenous fluid infusion rates.
- Encourage oral fluid intake when prescribed.
- Provide privacy when the patient is using bedpan, bedside commode, urinal, or bathroom.
- Initiate urinary catheterization, if prescribed.

Preventing Surgical Site Complications

The nurse assesses and cares for the surgical site to promote healing and prevent complications such as infection, dehiscence (wound closure separation), and evisceration (protrusion of intra-abdominal organs). Wound care is discussed in Chapter 33. Nursing interventions to prevent surgical site complications are assessing vital signs (especially for fever); maintaining hydration; maintaining nutritional status; encouraging a diet high in protein, carbohydrates, calories, and vitamins; using proper hand hygiene; and following aseptic technique when changing dressings at the surgical site and exit sites for tubes and drains. Dispose of soiled gloves and dressings following standard precautions.

Promoting a Return to Health

Nurses provide interventions during postoperative recovery to promote physical and psychological functioning at as near a normal state as possible. The plan of care to achieve this objective includes activities to meet elimination, fluid and electrolyte balance, nutrition, rest and comfort, and pain management needs.

ELIMINATION NEEDS

Both urinary and bowel elimination are altered by anesthesia. Manipulation of organs during surgery, inactivity, pain medication, and altered fluid and food intake all impact baseline bowel and bladder routines during the perioperative period. Assessments and nursing interventions to promote the return of normal bowel and urinary elimination are outlined in Box 31-6.

FLUID AND NUTRITION NEEDS

Nursing assessments and interventions to meet fluid needs include monitoring trends and balance of intake and output, maintaining prescribed IV fluid infusion rates, encouraging fluid intake, and assessing skin turgor and mucous membranes for fluid volume deficit. Nutritional needs are met by monitoring weight, providing oral hygiene before meals and as needed, facilitating postoperative dietary progression, maintaining an environment conducive to appetite (clean, neat, free of odors), encouraging the patient to sit up in a chair for meals, and encouraging family presence during meals. Nurses employ clinical judgment regarding patient tolerance of fluids and food to advance the patient's

diet—often from clear to full liquids, then from a soft to regular diet. Objective measures that inform decision-making postoperatively include presence of bowel sounds, flatus, diaphoresis, vomiting, diarrhea or constipation, abdominal distension, and review of an intake/output log. Subjective measures include the patient's reports of hunger, feelings of discomfort (nausea or pain), and interest in food. Refer to Chapter 37 for more insight into nutrition.

COMFORT AND REST NEEDS

Comfort is a priority after surgery. Factors that interfere with comfort include nausea, vomiting, thirst, hiccups, positioning in bed, room noise and temperature, and pain at the surgical site. Nursing interventions that promote rest and comfort by alleviating these problems are listed in Guidelines for Nursing Care 31-4 on page 1068. The nurse also promotes comfort by providing personal hygiene, keeping bed linens clean, maintaining a patient-preferred room temperature, providing quiet rest periods, and allowing family members to remain with the patient.

Helping the Patient Cope

Surgery may alter the patient's physical appearance as well as physiologic function, leading to the risk for or actual alterations in self-concept and body image. Changes in a person's self-perception can influence all of the human dimensions and areas of human functioning, including self-esteem, relationships with others, sexual identity, spiritual beliefs, sociocultural values, and independent and fulfilling engagement in activities of daily living.

Guidelines for Nursing Care 31-4

Promoting Postoperative Rest and Comfort

Nausea and Vomiting

- Avoid giving large amounts of fluids or food at one time, especially after being NPO.
- Administer prescribed medications.
- Provide oral hygiene, as needed.
- Maintain a clean environment.
- Avoid use of a straw.
- Avoid strong-smelling food.
- Assess for possible allergy or intolerance to medications, such as antibiotics or analgesics.
- Maintain bowel elimination.

Thirst

- Offer sips of water or ice chips when NPO (if permitted).
- Maintain oral hygiene.

Hiccups

- Have the patient do the following:
  - Take several swallows of water while holding the breath (if not NPO).
  - Rebreathe into a paper bag.
  - Eat a teaspoon of granulated sugar.
- Provide medications as prescribed.

Surgical Pain

- Assess pain frequently; administer prescribed analgesics every 2 to 4 hours on a regular schedule during the first 24 to 36 hours after surgery.
- Reinforce preoperative teaching for pain management.
- Offer nonpharmacologic measures to supplement medications: massage, position changes, relaxation, guided imagery, meditation, music.

Many surgical patients have the same reaction to loss of a body part as to a death (see Chapter 44). The response and adaptation to the loss are influenced by multiple factors, including age, cultural values and beliefs, sociocultural background, significance of the body part, visibility of the body part, time to prepare for the change, and support people available. A surgical patient's grief is a normal and appropriate response. It is unique to the person experiencing it, and although there are stages and phases of grief, there is no timetable for it. The nurse must be aware of the patient's needs and provide interventions to meet those needs in coping with change. Nursing interventions to facilitate coping and adaptation are outlined in Box 31-7.

Providing Outpatient/Same-Day Surgery Postoperative Care

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Evaluating the patient's postoperative status after outpatient/same-day surgery focuses on ensuring that the patient can be safely cared for at home. After surgery and recovery from the anesthetic, ask the patient to sit up and drink liquids. A patient who is no longer drowsy or dizzy, has stable vital signs, and has voided is allowed to go home accompanied by a responsible adult. The patient is not allowed to drive a car or go home alone on public transportation. The usual length of time from completion of surgery to discharge is 1 to 3 hours, provided that established criteria have been met. Give written and verbal instructions for home care to the patient and caregivers. Ask the patient and caregivers to *teach back* or provide a *return demonstration* to verify the patient's/caregiver's understanding. The patient and nurse both sign and date that these instructions were received, reviewed, and understood.

Box 31-7 Nursing Interventions to Facilitate Postoperative Coping and Adaptation

- Accept each patient as a unique person. Use appropriate pronouns and address the patient by their preferred name.
- Identify through verbal and nonverbal cues patients who are at risk for alteration in self-concept. The risk is increased if the patient has little support from others, a visible alteration, or an alteration that will seriously affect functional ability.
- Allow time for patients and families to verbalize their feelings about the alteration, and do not assume that all patients will have problems.
- Identify and support strengths and effective coping mechanisms.
- Encourage the patient and family to be part of goal setting and decision making throughout the surgical experience.
- Provide teaching and honest information to the patient and family about all aspects of care.
- Work collaboratively with other members of the health care team to provide referrals and resources as necessary to meet physical, psychological, and spiritual needs.

Evaluating

The nurse may evaluate the achievement of desired outcomes for postoperative recovery and rehabilitation in a number of ways. Because the final resolution of some desired outcomes may not be apparent or measurable at the time of discharge, many institutions use follow-up telephone calls or mailed surveys to patients. It may also be possible to collaborate with the health care provider's office to have a patient complete a survey on the first postoperative visit. Whatever mechanism is selected, include the following important outcomes as part of evaluative criteria: absence of surgical site infection, patient satisfaction with pain management measures, return to former levels of mobility and activity, absence of postoperative nausea and vomiting (PONV) at discharge, and absence of other complications for which the patient was at risk.

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the object of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop your expertise in evaluating the plan of care, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following:

- How aware are you of the developmental considerations regarding the perioperative phases? Are you able to articulate the populations are greatest risk during surgery?
- What value do you attach to involving and empowering the patient throughout the perioperative process? How do you individualize the care for patients when so many guidelines, policies, and procedures dictate your care? What are the key elements of nursing care during the pre-, intra-, and postoperative phases?
- What plan do you have to stay abreast of evolving standards and surgical procedures? What are the core principles of perioperative nursing that will exist irrespective of evolving technologies?

Keeping up with the latest evidence-based practice guidelines can be challenging. Ensuring you are tuned into the appropriate professional organizations and governmental facilities can help you stay on the cutting edge. Balancing the needs of each patient with these responsibilities requires mindfulness and intentionality.

Perhaps the most important questions to reflect on are: Are your patients and families better for having had *you* share in the critical responsibility of partnering with them to ensure appropriate perioperative care? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Skill 31-1 Providing Preoperative Patient Care

DELEGATION CONSIDERATIONS

Preoperative assessment and teaching are not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, preoperative teaching may be delegated to licensed practical/vocational nurses (LPN/LVNs) after an assessment of education needs by the registered nurse. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

Equipment (Varies, Depending on the Type of Surgery and Surgical Setting)

- Blood pressure cuff
- Electronic blood pressure monitor/sphygmomanometer
- Pulse oximeter
- IV infusion device
- Graduated compression stockings
- Pneumatic compression device
- Tubes, drains, vascular access tubing
- Incentive spirometer
- Small pillow
- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Check the patient's health record for the type of surgery and review the prescribed interventions. Review the nursing database, history, and physical examination. Check that the baseline data are recorded; communicate any assessment abnormalities or areas of concern to the health care team.	These checks ensure that the care will be provided for the right patient and any specific teaching based on the type of surgery will be addressed. Also, this review helps to identify patients who are at increased surgical risk.
2. **Check that all diagnostic testing has been completed and results are available; identify and communicate abnormal results to the health care team.** Gather the necessary supplies.	This check may influence the type of surgery performed and anesthetic used, as well as the timing of surgery or the need for additional consultation. Preparation promotes efficient time management and an organized approach to the task.
 3. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 4. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
5. Close the curtains around the bed and close the door to the room, if possible. Explain what you are going to do and why you are going to do it to the patient and significant other. Place necessary supplies on the bedside stand, overbed table, or other surface within easy reach.	Closing the curtains and door ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement. Bringing everything to the bedside conserves time and energy. Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
6. Explore the psychological needs of the patient and family/caregivers related to the surgery.	Meeting the psychological needs of the patient and family/caregivers before surgery can have a beneficial effect on the postoperative course.
a. Establish a therapeutic relationship, encouraging the patient to verbalize concerns or fears.	Use of therapeutic communication skills decreases anxiety (Croke, 2020a), promotes healing, enhances

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	safety, and improves clinical outcomes.
b. Use active listening skills, answering questions and clarifying any misinformation. c. Use touch, as appropriate, to convey genuine empathy.	
d. Offer to contact spiritual counselor (e.g., priest, minister, rabbi) to meet spiritual needs.	Spiritual beliefs for some patients and family/caregivers can provide a source of support over the perioperative course.
7. **Identify learning needs of patient and family/caregivers.** Ensure that the informed consent of the patient for the surgery has been signed, timed, dated, and witnessed. Inquire if the patient has any questions regarding the surgical procedure (Figure 1). Check the patient's record to determine if an advance directive has been completed. If an advance directive has not been completed, discuss with the patient the possibility of completing it, as appropriate. If patient has had surgery before, ask about this experience.	Patient education enhances surgical recovery and allays anxiety by preparing the patient for postoperative convalescence, discharge plans, and self-care (Croke, 2020b). The surgeon is responsible for explaining the details of the surgical procedure and potential risks and complications. The nurse is responsible for clarifying what the surgeon has explained to the patient and contacting the surgeon if the patient does not understand or has further questions. An advance directive provides written communication of the patient's wishes to the health care team related to the patient's desire for extraordinary life-sustaining treatments if the patient's condition is deemed unsalvageable. Previous surgical experience may impact preoperative care positively or negatively, depending on the patient's experience.

FIGURE 1. Identifying needs of patient and answering questions.

8. Teach deep-breathing exercises.	Deep-breathing exercises improve lung expansion and volume, help expel anesthetic gases and mucus from the airway, and facilitate the oxygenation of body tissues.
9. Teach coughing and splinting.	Coughing helps remove retained mucus from the respiratory tract. Splinting minimizes pain while coughing or moving.
10. Teach use of incentive spirometer, as prescribed or indicated.	Incentive spirometry improves lung expansion, helps expel anesthetic gases and mucus from the airway, and facilitates oxygenation of body tissues. Use of incentive spirometry may be based on patient risk factors and/or health care provider preference; evidence of effectiveness in prevention of postoperative pulmonary complications is controversial (Branson, 2013; Cassidy et al., 2020; Lumb, 2019; Strickland et al., 2013).

11. Teach leg exercises, as appropriate.	Physical activity reduces the risk of postoperative complications. Leg exercises assist in preventing muscle weakness, promote venous return, and decrease complications related to venous stasis. Leg exercises may be contraindicated for patients with certain conditions, such as lower extremity fractures.
12. Teach about early ambulation, as appropriate.	Physical activity reduces the risk of postoperative complications. Early ambulation has positive effects on the respiratory, cardiovascular, integumentary, musculoskeletal, gastrointestinal, and renal systems (Hinkle et al., 2022). Discussing the benefits during the preoperative period help patients fully engage in this activity (as appropriate) despite expected pain and discomfort postoperatively.
13. Assist the patient in putting on graduated compression stockings. Demonstrate how the pneumatic compression device operates.	Graduated compression stockings and pneumatic compression devices are used postoperatively for patients who are at risk for a deep vein thrombosis (DVT) and pulmonary embolism (AORN, 2018; Fan et al., 2020; Hinkle et al., 2022; Tubog, 2019).
14. Teach about turning in the bed.	Turning and repositioning of the patient is important to prevent postoperative complications and to minimize pain.
a. Instruct the patient to use a pillow or bath blanket to splint where the incision will be. Ask the patient to raise their left knee and reach across to grasp the right side rail of the bed. If the patient is turning to the left side, they will bend the right knee and grasp the left side rail.	
b. When turning the patient onto the right side, ask the patient to push with bent left leg and pull on the right side rail (Figure 2). Explain to the patient that you will place a pillow behind his/her back to provide support, and that the call bell will be placed within easy reach.	
c. Explain to the patient that position change is recommended every 2 hours.	

FIGURE 2. Helping the patient roll over to her right side while she pushes with left bent leg and pulls on the side rail.

15. Provide individualized, developmentally appropriate teaching about pain management options, plans and goals.	Individualized use of pharmacologic and nonpharmacologic methods of pain management is an important part of pain management guidelines related to surgery (Chou et al., 2016). Adequate pain control is important; continuing or unresolved pain can increase the patient's length of recovery and delay discharge.
a. Discuss past experiences with pain and	Past experiences with pain can impact the patient's

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

interventions that the patient has used to reduce pain.	ability to manage surgical pain. Pain is a subjective experience and the interventions effective in reducing pain vary from patient to patient.
b. Discuss the availability of analgesic medication post-operatively.	Depending on the prescribed interventions, the patient may need to request analgesic medication, as needed, or a patient-controlled analgesia (PCA) or epidural analgesia may be prescribed, for which the patient will need specific instruction on how to use.
c. Discuss the use of PCA, as appropriate.	Patient understanding of the use of PCA is crucial for effective, safe administration.
d. Explore the use of other alternative and nonpharmacologic methods to reduce pain, such as position change, massage, relaxation/diversion, guided imagery, and meditation.	These measures may reduce anxiety and may decrease the amount of pain medication that is needed. Analgesic therapy should involve a multimodal approach influenced by age, weight, and comorbidity.
16. Review equipment that may be used after surgery.	
a. Show the patient various equipment, such as IV infusion devices, electronic blood pressure cuff, tubes, urinary catheters, and surgical drains.	Knowledge can reduce anxiety about equipment and upcoming experiences. The patient may need an indwelling urinary catheter during and after surgery to keep the bladder empty and to monitor urinary output. Drains are frequently used to remove excess fluid around the surgical incision.
17. Provide skin preparation.	
a. **Ask the patient to bathe or shower with the antibacterial soap or solution. Remind the patient to clean the surgical site.** An antiseptic shower, bath, or cleansing with antimicrobial-impregnated wipes may be prescribed the evening before surgery and repeated the morning of surgery to begin the process of preparing the skin before surgery and to prevent infection (Mok et al., 2019; Parry, 2018). The skin is cleaned at the operative site with an antibacterial soap or solution to remove microorganisms. The patient can do this while taking a bath or shower. The specific choice of soap or antiseptic product depends on the patient, the procedure, and the manufacturer recommendations (AORN, 2020). This skin antiseptic eliminates skin microorganisms and leaves an antimicrobial film on their skin.	Evidence-based practice advises against hair removal at the surgical site due to increased potential for infection. If hair removal is necessary, it should be accomplished using hair clippers and be performed immediately before the surgery, in a patient care room outside the operating room, using disposable supplies and aseptic technique (AORN, 2020, as cited in Spruce, 2020a, p. 82). Follow facility policy regarding skin preparation of the surgical patient. In addition, immediately before the surgical procedure, the skin of the patient's operative site will be cleansed with a product that is compatible with the antiseptic used for showering.
18. Provide teaching about and follow dietary/fluid restrictions. **Explain to the patient that both food and fluid will be restricted before surgery to ensure that the stomach contains a minimal amount of gastric secretions. This restriction is important to reduce the risk of aspiration. Emphasize to the patient the importance of avoiding food and fluids during the prescribed time period, because failure to adhere may necessitate cancellation of the surgery.**	Ensure that fluid and dietary restrictions (NPO), as prescribed or as per facility protocol, have been followed. These restrictions assist in preventing aspiration (Hinkle et al., 2022).
19. Provide intestinal preparation, as appropriate. In certain situations, such as surgery of the lower gastrointestinal tract or pelvic surgery, the bowel will need to be prepared by administering enemas or laxatives.	A prescribed bowel prep and cleansing enema may be prescribed if the patient is scheduled for surgery of the lower gastrointestinal tract to evacuate the bowel and to reduce the intestinal bacteria to help prevent contamination of the surgical area during surgery. Peristalsis may not return for 24 to 48 hours after the bowel is handled, so preoperative cleansing also helps to decrease postoperative constipation.

a. As needed, explain the purpose of enemas or laxatives before surgery. If the patient will be administered an enema, clarify the steps as needed.	Enemas can be stressful, especially when repeated enemas are required to obtain a clear fluid return. Repeated enemas may cause fluid and electrolyte imbalance, orthostatic hypotension, and weakness.
20. **Check and verify administration of regularly scheduled medications.** Review with the patient routine medications, over-the-counter medications, and herbal supplements that are taken regularly. Check the prescribed interventions and review with the patient which medications they should take and those they should not take the day of surgery.	Many patients take medications for a variety of chronic medical conditions. Adjustments in taking these medications may be needed before surgery. Certain medications, such as aspirin, are stopped days before surgery due to their anticoagulant effect. Certain cardiac and respiratory drugs may be taken the day of surgery per prescribed intervention. If the patient has diabetes, oral hypoglycemic agent and/or insulin dosages may be reduced.
21. Provide information to the patient and family/caregivers regarding timing of surgical events and potential sensations that may be experienced. Explain to patients and their families how long the surgery and postanesthesia care will last, as well as what will be done before, during, and after surgery (e.g., procedures, medications, equipment). Explain to patients that they may not drive themselves home or take public transportation alone if they have had any anesthesia or sedation.	Patients and their families require this information to plan activities accordingly. Explanation and knowledge relieve anxiety and facilitates engagement.
 22. Remove PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Document that the patient's health records were reviewed, including the history, physical assessment, and any laboratory values and diagnostic studies. Record that the health care team was notified of any abnormal values. Document the components of perioperative teaching that were reviewed with the patient and family/caregivers, if present, such as use of the incentive spirometer, deep-breathing exercises, splinting, leg exercises, graduated compression stockings, and pneumatic compression devices. Record the patient's ability to demonstrate the skills and response to the teaching, and note if any follow-up instruction needs to be performed. Document other preoperative teaching, including pain management, intestinal preparation, medications, and preoperative skin preparation. Record any patient concerns about the surgery and whether the surgeon/health care team was contacted to provide any further explanations. Document the emotional support that was offered to the patient and if a spiritual counselor was notified per request of patient.

Sample Documentation

4/2/25 1030 Patient's health records were reviewed, and no abnormal results were identified. Perioperative teaching points reviewed with patient and his wife, including the rationale for each of these points. Patient demonstrated proper deep breathing, splinting while coughing, and leg exercises. Reviewed pain management, intestinal preparation, medications, and preoperative skin preparation. Patient stated that he was anxious about the surgery because this will be his first time to the OR. Emotional support and reassurance were provided.

—J. Grabes, RN

Developing Clinical Reasoning and Clinical Judgment

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient's laboratory results are noted to be abnormal:* Notify health care team. Some abnormalities, such as an elevated international normalized ratio (INR) or abnormalities in the complete blood count (CBC), may postpone the surgery.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- *Patient says to you, "I'm not sure I really want this surgery":* Ask the patient to elaborate on their concerns. Discuss with the patient why they feel this way. Notify the health care team. Patients should not undergo surgery until any questions or doubts are resolved and they are sure that surgery is what they want.

SPECIAL CONSIDERATIONS

General Considerations

- Patients who are obese are at increased risk for respiratory and cardiovascular compromise as well as an increased incidence of gastroesophageal reflex disease, hiatal hernia, and abdominal pressure that puts them at increased risk for aspiration of stomach contents (AORN, 2020). In taking the history of these patients, be alert for other medical conditions, such as diabetes, cardiovascular disease, respiratory disease, kidney disease, and liver disease, which also increase the risk of surgical complications.
- Current recommendations caution against routine opioid prescription postoperatively, focusing on oral opioid administration with acetaminophen and/or nonsteroidal anti-inflammatory drugs (NSAIDs) as needed, or the use of patient-controlled analgesia (PCA) when the parenteral route is necessary (Chou et al., 2016).

Infant and Child Considerations

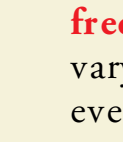
- Children have special needs related to their overall health, age, and size. Easing preoperative anxiety of the child is crucial and includes using simple and concrete terms when providing information (Aranha & Dsouza, 2019; Kyle & Carman, 2021).
- The nurse needs to be sensitive to the anxiety level of the parent and provide support, explanations, and patient teaching, as needed (Aranha & Dsouza, 2019; Kyle & Carman, 2021).
- Accurate weights are essential for correct medication dosages (Kyle & Carman, 2021).
- Developmentally appropriate pain assessment and management needs to be initiated to ensure adequate pain management (Kyle & Carman, 2021).

Older Adult Considerations

- Age-related changes and pre-existing chronic conditions can affect the postoperative course of the older adult patient (Eliopoulos, 2018).
- It is important to present preoperative teaching information slowly with reinforcement, because processing of information can be slower (Bastable, 2017).
- Management of postoperative pain in older adults may be complicated by a number of factors, including a higher risk of age- and disease-related changes in physiology and disease–drug and drug–drug interactions (Karch, 2020).

Skill 31-2 Providing Postoperative Care

DELEGATION CONSIDERATIONS



Postoperative measurement of vital signs may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). Postoperative assessment and teaching are not delegated to AP. Depending on the state's nurse practice act and the organization's policies and procedures, postoperative teaching may be delegated to LPN/LVNs after an assessment of education needs by the registered nurse. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

Equipment (Varies, Depending on the Surgery)

- Electronic blood pressure monitor/sphygmomanometer
- Blood pressure cuff
- Electronic thermometer
- Pulse oximeter
- Stethoscope
- IV infusion device, IV solutions
- Graduated compression stockings (as prescribed/indicated)
- Pneumatic compression devices (as prescribed/indicated)
- Tubes, drains, vascular access tubing

- Incentive spirometer (as prescribed/indicated)
- PPE, as indicated
- Blankets and/or forced-air warming device, as needed

IMPLEMENTATION

ACTION	RATIONALE
Immediate Care	
1. When the patient returns from the PACU, participate in hand-off report from the PACU nurse and review the OR and PACU data. Gather the necessary supplies.	Obtaining a hand-off report ensures accurate communication and promotes continuity of care. Preparation promotes efficient time management and an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Close the curtains around the bed and close the door to the room, if possible. Explain what you are going to do and why you are going to do it to the patient or significant other. Place necessary supplies on the bedside stand, overbed table, or other surface within easy reach.	Closing the curtains and door ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement. Bringing everything to the bedside conserves time and energy. Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
5. **Place the patient in safe position (semi- or high-Fowler's or side-lying). Note level of consciousness.**	A head of bed (HOB)-elevated position facilitates deep breathing; the side-lying position with neck slightly extended prevents aspiration and airway obstruction. Alternate positions may be appropriate based on the type of surgery.
6. **Obtain vital signs. Monitor and record vital signs frequently.** Prescribed assessment frequency may vary, but usual frequency includes taking vital signs every 15 minutes the first hour, every 30 minutes the next 2 hours, every hour for 4 hours, and finally every 4 hours. Refer to facility policy and adjust based on patient circumstances and nursing clinical judgment (AORN, 2019). Temperature measurement should be obtained using the same site and method of measurement (AORN, 2019). If continuous vital sign monitoring is used, apply monitor per manufacturer's directions.	Comparison with baseline preoperative vital signs may indicate impending shock, respiratory compromise, or hemorrhage. Although protocols are used as guidelines in the immediate postoperative period, the nurse is responsible for adjusting the frequency and priorities of assessment to the specific needs of each patient. Temperature measurement can vary significantly when temperatures are measured at different sites or by different methods; the same site and method of temperature measurement should be used throughout the perioperative phases when clinically feasible (AORN, 2019). Wireless continuous vital sign monitoring maybe used to aid in early detection of changes in the patient's condition (Downey et al., 2018; Verillo et al., 2019).
7. Assess the patient's respiratory status. Measure the patient's oxygen saturation level (Figure 1). If oxygen is prescribed or warranted, ensure accurate delivery device and flow rate. Measure and monitor the patient's end-tidal carbon dioxide levels as prescribed or based on facility policy.	Comparison with baseline preoperative respiratory assessment may indicate impending respiratory complications. Pulse oximetry provides information about the patient's oxygenation status. Measurement of end-tidal carbon dioxide levels (capnography) provides information about the patient's ventilation status and may be used to monitor patients with known or suspected obstructive sleep apnea and those who receive sedation and opioids or other CNS depressants (Borczynski & Worobel-Luk, 2019;

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

		Burns & Delgado, 2019; Hess et al., 2021).
8.	Assess the patient's cardiovascular status.	Comparison with baseline preoperative cardiovascular assessment may indicate impending cardiovascular complications.
9.	Assess the patient's neurovascular status, based on the type of surgery performed.	Comparison with baseline preoperative neurovascular assessment may indicate impending neurovascular complications.
10.	Provide for warmth, using heated or extra blankets, or forced-air warming device as necessary. Assess skin color and condition.	The OR is a cold environment. All perioperative patients are at risk for hypothermia (AORN, 2019). Hypothermia is uncomfortable, and it is associated with prolonged postoperative recovery, cardiac arrhythmias, impaired renal function, and impaired wound healing (Hinkle et al., 2022; Link, 2020; Nieh & Su, 2018; Xu et al., 2019).
11.	Put on gloves. Assess the surgical site. Check dressings for color, odor, presence of drains, and amount of drainage (Figure 2). Mark the drainage on the dressing by circling the amount and include the time. Assess dependent areas, such as turning the patient to assess visually under the patient, for bleeding from the surgical site.	Hemorrhage and shock are life-threatening complications of surgery and early recognition is essential.

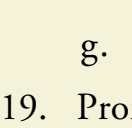


FIGURE 1. Obtaining postoperative oxygen saturation level.

FIGURE 2. Checking dressings for color, odor, and amount of drainage.

12.	Verify that all tubes and drains are patent, and the equipment is working; note the amount of drainage in collection device. If an indwelling urinary catheter is in place, note urinary output.	This ensures function of drainage devices.
13.	Verify and maintain IV infusion at prescribed rate.	This replaces fluid loss and prevents dehydration and electrolyte imbalances.
14.	Assess for pain. Check health record to verify if analgesic medication was administered in the PACU. Administer analgesics as indicated, prescribed, and appropriate. If the patient has been instructed in the use of PCA for pain management, review its use. Institute nonpharmacologic pain management interventions as appropriate and indicated.	Use a facility-approved pain scale (Chou et al., 2016). Observe for nonverbal behavior that may indicate pain, such as grimacing, crying, and restlessness. Analgesics and other nonpharmacologic pain strategies are used for relief of postoperative pain.
15.	Assess for nausea and vomiting. Administer antiemetic medication as indicated, prescribed, and appropriate. Institute nonpharmacologic management interventions as appropriate and indicated.	General anesthesia can cause postoperative nausea and vomiting. Vomiting can lead to serious complications, including pulmonary aspiration, dehydration, and dysrhythmias secondary to electrolyte imbalances (Koyuncu et al., 2020). Aromatherapy has been suggested as a complementary intervention to decrease postoperative nausea and vomiting (Abril et al., 2019; Karaman et al., 2019; Spruce, 2020b).

16. Provide for a safe environment. Keep the bed in low position with the side rails up, based on facility policy. Have the call bell within patient's reach.	This adjustment to the bed prevents accidental injury. Easy access to the call bell permits the patient to call for nurse when necessary.
 17. Remove PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.
Ongoing Care	
18. Promote optimal respiratory function.	The patient is at risk for respiratory complications postoperatively. Interventions can be implemented to prevent respiratory complications.
a. Assess respiratory rate, depth, quality, color, and capillary refill. Ask if the patient is experiencing any difficulty breathing.	The patient is at risk for pulmonary complications postoperatively. Postoperative analgesic medication can reduce the rate and quality of the respiratory effort. Interventions can be implemented to prevent cardiovascular complications.
b. Assist with coughing and deep-breathing exercises.	
c. Assist with incentive spirometry, as indicated/prescribed.	
d. Assist with early ambulation.	
e. Provide frequent position changes.	
f. Administer oxygen, as prescribed.	
g. Monitor pulse oximetry.	
19. Promote optimal cardiovascular function:	Patient is at risk for cardiovascular complications postoperatively. Interventions can be implemented to prevent cardiovascular complications.
a. Assess apical rate, rhythm, and quality and compare with peripheral pulses, color, and blood pressure. Ask if the patient has any chest pains or shortness of breath.	
b. Provide frequent position changes.	
c. Assist with early ambulation.	
d. Apply graduated compression stockings or pneumatic compression devices, if prescribed and not in place. If in place, assess for integrity.	
e. Provide leg and range-of-motion exercises if not contra-indicated.	
20. Promote optimal neurologic function:	Anesthetic and pain management agents can alter neurologic function. Sedation scales are used to assess sedation levels and provide nurses with a useful tool to make decisions about the timing of medication interventions and when to intervene based on patients' sedation levels (Hall & Stanley, 2019).
a. Assess level of consciousness, movement, and sensation. Assess and monitor the patient's level of sedation using a sedation scale, particularly if opioids are used to treat postoperative pain (Hall & Stanley, 2019).	
b. Determine the level of orientation to person, place, and time.	
c. Test motor ability by asking the patient to move	Anesthesia alters motor and sensory function.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

each extremity.	
d. Evaluate sensation by asking the patient if they can feel your touch on an extremity.	
21. Promote optimal renal and urinary function and fluid and electrolyte status. Assess intake and output, evaluate for urinary retention and monitor serum electrolyte levels.	Anesthetic agents and surgical manipulation in the area may temporarily depress bladder tone and response causing urinary retention.
a. Promote voiding by offering bedpan/bedside commode, or assistance to bathroom at regular intervals, noting the frequency, amount, and if any burning or urgency symptoms.	Frequency, burning, or urgency may indicate possible urinary tract abnormality.
b. Monitor urinary catheter drainage if present.	Communicate with the health care team if the patient's urinary output is less than 30 mL/hr or 240 mL/8-hr period.
c. Measure intake and output.	Intake and output are good indicators of fluid balance.
22. Promote optimal gastrointestinal function and meet nutritional needs:	Anesthetic agents and opioids depress peristalsis and normal functioning of the gastrointestinal tract (Karch, 2020). Flatus indicates return of peristalsis.
a. Assess abdomen for distention and firmness. Ask if patient feels nauseated, any vomiting, and if passing flatus.	
b. Auscultate for bowel sounds.	Presence of bowel sounds indicates return of peristalsis.
c. Assist with diet progression; encourage fluid intake; monitor intake.	Patients may experience nausea after surgery and are encouraged to resume diet slowly, starting with clear liquids and advancing as tolerated.
d. Medicate for nausea and vomiting, as prescribed. Institute nonpharmacologic interventions as appropriate and indicated.	Antiemetics are frequently prescribed to alleviate postoperative nausea. Complementary interventions may be effective in decreasing nausea and vomiting.
23. Promote optimal wound healing.	Alterations in nutritional, circulatory, and metabolic status may predispose the patient to infection and delayed healing.
a. Assess condition of wound for presence of drains and any drainage.	
b. Use surgical asepsis for dressing changes and drain care.	Surgical asepsis reduces the risk of infection.
c. Inspect all skin surfaces for beginning signs of pressure injury and use pressure-relieving supports to minimize potential skin breakdown.	Lying on the OR table in the same position can predispose some patients to pressure injury formation, especially in patients who have undergone lengthy procedures.
24. Promote optimal comfort and relief from pain.	This shortens recovery period and facilitates return to normal function.
a. Assess for pain (location and intensity using pain scale).	Control of postoperative pain promotes patient comfort and recovery.
b. Provide for rest and comfort; provide extra blankets, as needed, for warmth.	Patients may experience chills in the postoperative period.
c. Administer analgesics, as needed, and/or initiate nonpharmacologic methods, as appropriate.	Multimodal analgesia, combining analgesic drugs from different classes, is recommended to reduce the risk of adverse drug effects (Polomano et al., 2017; Poulsen et al, 2019).
25. Promote optimal outcomes related to psychosocial needs:	This facilitates individualized care, anxiety reduction, and patient's return to normal health.
a. Provide emotional support to patient and family/caregivers, as needed.	

b. Explain procedures and offer explanations regarding postoperative recovery, as needed, to both patient and family members/caregivers.

Documentation

Guidelines

Document the time that the patient returns from PACU to the surgical unit. Record the patient's level of consciousness, vital signs, all assessments, and condition of dressing. If patient has oxygen in place, an IV, or any other equipment, record this information. Document pain assessment, interventions that were instituted to alleviate pain, and the patient's response to the interventions. Document any patient teaching that is reviewed with the patient, such as use of incentive spirometer.

Sample Documentation

4/10/25 1330 Patient returned to room at 1315, drowsy but easily aroused; answers to name. Patient's temperature 98.8°F, pulse 78, BP 122/84, O_2 sat 96% on O_2 2 L/min. Right lower abdominal dressing dry and intact. Rates pain at a "4" on a scale of 1 to 10, was medicated in PACU with 4-mg morphine sulfate IV at 1030. Incentive spirometry completed × 10 cycles, 750 mL each. Patient deep breathing and coughing without production and turned to right side with HOB elevated. See EHR for additional system assessments.

—J. Grabbs, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Vital signs are progressively increasing or decreasing from baseline:* Collaborate with the health care team. A continued decrease in blood pressure or an increase in heart rate could indicate internal bleeding or **hemorrhage**.
- *Dressing was clean before but now has large amount of fresh blood:* Do not remove dressing. Reinforce dressing with more bandages. Removing the bandage could dislodge any clot that is forming and lead to further blood loss. Consult with the health care team.
- *Patient reports pain that is not relieved by prescribed medication:* After fully assessing pain, consult with the health care team. Pain can be a clue to other problems, such as hemorrhage.
- *Patient is febrile within 12 hours of surgery:* Assist patient with coughing and deep breathing. If prescribed, encourage incentive spirometry. Continue to monitor vital signs and laboratory values such as complete blood count (CBC).
- *Adult patient has a urine output of less than 30 mL/hr:* Unless this is expected, consult with the health care team. Urine output is a good indicator of tissue perfusion. Patient may need more fluid or may need medication to increase blood pressure if blood pressure is low.

SPECIAL CONSIDERATIONS

General Considerations

- Be aware of baseline sensory deficits. Ensure appropriate aids are in place, such as glasses or hearing aids. Lack of appropriate aids may impact postoperative assessments, such as level of consciousness.
- For patients undergoing throat surgery, such as a tonsillectomy, evaluate swallowing pattern. A patient who has had throat surgery and swallows frequently may be bleeding from the incision site.
- Multimodal analgesia, which combines analgesic drugs from different classes and employs analgesic techniques that target different mechanisms of pain, is recommended in the treatment of acute postoperative pain. The synergistic effects maximize pain relief at lower analgesic doses, reducing the risk of adverse drug effects (Polomano et al., 2017, p. S12).
- Consider the need for a bariatric mattress or bariatric bed for a patient who is obese because this patient is at greater risk for alterations in skin integrity due to the poor vascular supply of adipose tissue and restrictions in movement (Hinkle et al., 2022).
- Intermittent manual vital sign measurement as single data points may provide an incomplete picture of patients' postoperative physiologic status (Downey et al., 2018; Verrillo et al., 2019). Wearable sensor packs using wireless technology are being used in some settings for continuous measurement of vital signs. This monitoring provides trending of vital signs (such as heart rate, respiratory rate, noninvasive blood pressure, temperature, and pulse oximetry) and may help in early detection of patient deterioration and improve patient outcomes (Verrillo et al., 2019).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Aromatherapy has been used successfully to decrease postoperative nausea and vomiting. Inhalers using essential oils, including peppermint, ginger, lavender, rose and spearmint oils, or a blend of these oils, have been shown to be effective (Abril et al, 2019; Karaman et al., 2019; Spruce, 2020b).
- Ensure that written postoperative instructions specific to the patient and follow-up appointments with the surgeon or other health care professionals are provided to each patient upon discharge from the hospital or outpatient center. Information, such as signs and symptoms to report to the health care team, as well as restrictions in activity and diet, are addressed. In addition, patients discharged the same day as their surgery are required to have a responsible person accompany them home, and a contact telephone number is to be provided in case of emergency. The patient should be alert and oriented, or mental status should be at the patient's baseline. The vital signs of the patient should be stable. Have the patient "teach back" important information/instructions in their own words.

Infant and Child Considerations

- Postoperative complications are often related to the respiratory system in this age group. After receiving general anesthesia, premature infants are at greater risk for apnea (Subramaniam, 2019).
- Infants and children are at great risk for temperature-related complications because their body temperature can change rapidly. It is essential to have warmed blankets and other warming equipment available to avoid this complication.

Older Adult Considerations

- Older adults may take longer to return to normothermia and their baseline level of orientation. Drugs and anesthetics may delay this return.
- Forced-air warming systems are suggested as the most effective means of rewarming older patients with postoperative hypothermia (Xu et al., 2019).

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Work through the Evolving Case Study 31-1 to help develop your clinical reasoning and clinical judgment skills.
. You are providing the immediate preoperative care for a woman scheduled for surgery to remove a brain tumor. She tells you she does not want the surgery because she knows she is dying and just wants to go home to be with her husband and children. She also knows that her husband cannot accept the fact that she is dying and wants her to have the surgery. What do you do?
. You are assigned to discharge a woman from your same-day surgery unit to her home. You strongly believe that she is not ready to go home, and there is no caregiver in her home. When you voice your concern to the surgeon, you are told that this is not your problem and that there is nothing anyone can do about the situation because her insurer will not approve hospitalization. How do you respond?

EVOLVING CASE STUDY 31-1

Scenario: Gabrielle McAllister, a 5-year-old admitted for removal of her tonsils and adenoids in same-day surgery, arrives at the outpatient surgery center with her mother. Gabrielle is clinging to her mother and quietly crying. Her mother says, "I don't think I can stand this again, but I know it has to be done."

QUESTION r/t CUES: As the initial point of contact for Gabrielle and her mother, what should the nurse say to begin the nurse–patient relationship?

A. "Mom, I know you are stressed, but you know the routine by now!"
B. "Hi, Gabrielle, my name is Emily, and I'm your nurse. Can you tell me something you like to do for fun with your family?"
C. "Gabrielle, this is my stethoscope. I'm going to listen to your heart and lungs."
D. "Hi, Gabrielle and Mom. I need you to calm down so we can get you ready for the big surgery."

Scenario: After some time and rapport formation, Gabrielle relaxes enough for the nurse to begin an assessment. The admitting nurse notes that Gabrielle is a 5-year-old female, who is small for her age. The child has a history of several previous surgeries for a congenital cardiac defect and a known latex allergy. Assessment parameters from a head-to-toe assessment are generally within normal limits. Gabrielle's lymph nodes in her neck are slightly swollen and her tonsils are visibly enlarged, but she denies difficulty breathing or swallowing at the moment. She reports a "little bit of a sore throat" and general throat/neck discomfort. Gabrielle has not had anything to eat or drink since she went to sleep last night.

QUESTION r/t ANALYZING CUES: Which information from this initial preoperative assessment is most important to convey to the professional administering the anesthesia and the intraoperative team?

A. Documented latex allergy
B. Gabrielle's emotional state

C. History of previous surgeries
D. System by system assessment data

Scenario: The nurse returns to the room and finds that Gabrielle is calm and cooperative, but still won't let go of her mother.

QUESTION r/t PRIORITIZING HYPOTHESIS: Based on the objective and subjective assessment of this patient, which priority problem should the nurse identify to guide the perioperative plan of care?

A. Bleeding risk
B. Activity intolerance
C. Acute anxiety
D. Thermal injury risk

Scenario: As they talk and the perioperative outcomes are identified, Gabrielle's mother starts talking about the transition of care to the operating room itself. Gabrielle climbs in her mom's lap and begins to yell, "No … No … you're not leaving me!"

QUESTION r/t GENERATING SOLUTIONS: Which solution is reasonable and safe for this transition of care?

A. Gabrielle's mom will be given time alone with Gabrielle in the preoperative room to provide comfort to Gabrielle
B. Gabrielle's mom will accompany Gabrielle to the surgical suite and remain with Gabrielle until the inhaled anesthesia takes effect
C. Gabrielle's mom will be at the preoperative bedside while the nurse initiates IV therapy and administers an IV sedative
D. Gabrielle's mom will administer an oral sedative to Gabrielle under the supervision of the nurse

Scenario: The nurse continues to build rapport with Gabrielle and her mother, and feels confident that they can review some key preoperative teaching that will be needed in the immediate postoperative phase.

QUESTION r/t TAKING ACTION: Which content and teaching modality best fit this particular situation?

A. Have Gabrielle use the incentive spirometer while providing direction and encouragement
B. Show Gabrielle the OR suite, taking time to point out the equipment and lights
C. Have Gabrielle perform a series of arm and neck stretches
D. Talk to Gabrielle and her mom about the likelihood of postoperative nausea and vomiting

Scenario: Gabrielle is taken to the OR suite. She is "nervous," but smiles when told by the CRNA that it's time to "get those tonsils out and eat lots of popsicles."

QUESTION r/t EVALUATING OUTCOMES: The nurse documents attainment of expected outcomes in the preoperative phase as part of the perioperative plan of care. Which outcomes were met for Gabrielle? Select all that apply.

A. Correct return demonstration of postoperative activities designed to prevent complications
B. Physical and emotional readiness for operative procedure; appropriate for age
C. Decreased risk for surgical site, catheter-based, and community-acquired infections
D. Caregiver articulation of when to call the provider for follow-up and/or intervention
E. Pulse oximetry >98% on room air

PRACTICING FOR NCLEX

. A nurse in the PACU is preparing to receive a patient from surgery who sustained a ruptured spleen in a motor vehicle accident. Which of these system assessments will take priority?

- Electronic Health Record: Operative Note
- Splenectomy secondary to trauma
- Estimated blood loss 900 mL

a. Neurologic system, ambulatory function
b. Cardiovascular system, vital signs
c. GI system, bowel function
d. Integumentary, skin breakdown

. A nurse is preparing a patient for a cesarean birth using spinal anesthesia. Which effects of anesthesia will the nurse teach the patient to expect? Select all that apply.

a. Loss of consciousness

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

b. Inability to speak
c. Reduction or loss of deep tendon reflexes
d. Loss of sensation below the injection
e. Inability to move the lower extremities
f. Prolonged pain relief after other anesthesia wears off

. A nurse has been asked to witness a patient signature on an informed consent form for surgery. What communication from the surgeon does the nurse expect the patient to receive before signing the form? Select all that apply.

a. Option of nontreatment
b. Underlying disease process and its natural course
c. Notice that once the form is signed, the patient cannot withdraw the consent
d. Explanation of the guaranteed outcome of the procedure or treatment
e. Name and qualifications of the provider of the procedure or treatment
f. Explanation of the risks and benefits of the procedure or treatment

. An older adult who is scheduled for a hip replacement is taking several medications on a regular basis. Which group of medications does the nurse identify as a surgical risk for this patient?

a. Anticoagulants
b. Antacids
c. Laxatives
d. Sedatives

. A nurse is caring for a patient who is obese and has had abdominal surgery. The nurse prioritizes a plan to prevent what postoperative complication?

a. Anesthetic interactions
b. Impaired wound healing
c. Weight gain
d. Flatulence

. When caring for a patient who returned from the operating room 8 hours ago, which finding requires follow-up assessment by the nurse?

a. Patient reports discomfort at surgical site, scale of 5/10
b. Patient voids small amounts every 20–30 minutes
c. Patient is sleepy and awakens only to touch
d. Patient reports thirst and dry mouth

. A nurse is providing teaching for a patient scheduled to have same-day surgery. Which teaching method would be most effective in preoperative teaching for ambulatory surgery?

a. Lecture
b. Discussion
c. Audiovisuals
d. Written instructions

. An adult patient awaiting surgery says to the nurse, “I am so frightened—what if I don’t wake up?” What is the nurse’s best response?

a. “Are you worried about the anesthesia?”
b. “Tell me what concerns you most.”
c. “Your surgeon is great; she operated on my aunt!”
d. “Many people are anxious before surgery.”

. During preoperative teaching about pain management, the patient asks the nurse to explain how a PCA pump works. What will the nurse teach the patient about PCA?

a. “It allows the patient to be completely free of pain during the postoperative period.”
b. “It allows the patient to take unlimited amounts of medication as needed.”
c. “It allows the patient to choose the type of medication given postoperatively.”
d. “It permits the patient to self-administer limited doses of pain medication.”

. A nurse is planning caring for a patient who had thoracic surgery. Which nursing interventions are most appropriate for patients undergoing this type of surgery?

a. Observing for incisional wound healing
b. Monitoring vital signs, especially pulse and blood pressure

c. Instructing the patient on the proper use of the incentive spirometer
d. Applying antiembolism stockings

. While assessing a patient in the PACU following abdominal surgery, a nurse promptly contacts the surgeon for which of these findings? Select all that apply.
Electronic Health Record
Vital signs

- 1200: T 97.4, P-89, RR 12, BP/102/70
- 1215: T 97.4, P-92, RR 12, BP/100/68
- 1230: T 97.2, P-112, RR 12, BP/98/60

Intake Output/Hemovac

- 1200: 200 mL 0.9% saline infused 30 mL sanguineous material
- 1215: IV NSS 25 mL 45 mL serosanguineous material
- 1230: IV NSS 25 mL 250 mL bright red blood

a. Tachycardia
b. IV with normal saline solution
c. Wound drainage
d. Patient restless
e. Patient reports incisional pain 8/10

. A nurse is caring for a postoperative patient who has been on bedrest for 5 days. What interventions will the nurse use to prevent deep vein thrombosis (DVT)? Select all that apply.
a. Administering analgesics
b. Documenting daily calf circumference
c. Assessing vital signs every 4 hours
d. Encouraging ambulation
e. Applying intermittent pneumatic compression devices (IPCDs)
f. Providing education on pain management

. A scrub nurse is assisting a surgeon with a kidney transplant. What are the patient responsibilities of the scrub nurse? Select all that apply.
a. Maintaining sterile technique
b. Draping and handling instruments and supplies
c. Identifying and assessing the patient on admission
d. Integrating case management
e. Preparing the skin at the surgical site
f. Providing exposure of the operative area

. A nurse on a surgical unit is aware that older adults develop reduced vital capacity as a result of normal physiologic changes. Based on these changes, which nursing intervention takes priority?
a. Taking and recording vital signs every shift
b. Turning, coughing, and deep breathing every 4 hours
c. Encouraging increased intake of oral fluids
d. Assessing bowel sounds daily

. A nurse teaches a patient the rationale for performing leg exercises after surgery. How does the nurse best explain the purpose of the exercises to the patient?
a. Improves respiratory function
b. Maintains functional abilities
c. Provides diversional activities
d. Increases venous return

. A nurse is preparing a patient for same-day surgery. Which of these patient-related findings must the nurse report immediately?
a. Asking how long after the surgery they can leave the hospital
b. Received an oral anticoagulant last night
c. Surgeon has not yet filled out the consent form
d. Blood pressure is 142/86

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

ANSWERS WITH RATIONALES

. **b.** The priority assessment focuses on the ruptured organ, blood loss, and monitoring for early signs of shock. Tachycardia, the first sign of shock, and decreasing blood pressure must be immediately reported to the health care provider. The neurologic system may be affected due to anesthesia, but ambulatory function is not the immediate priority. The nurse anticipates reduced or absent bowel sounds after surgery, but risk for blood loss is the priority. The nurse plans to promote wound healing and repositions the patient to prevent skin breakdown; however, hemorrhage and early detection of shock is the priority at this time.

. **d, e.** A localized loss of sensation, loss of motor function, and possible loss of reflexes occur with a regional anesthetic. Loss of consciousness, including speech and relaxation of skeletal muscles, occurs with general anesthesia. Prolonged pain relief after other anesthesia wears off and infiltration of the underlying tissues in an operative area occur with topical anesthesia.

. **a, b, e, f.** The information communicated while obtaining informed consent includes the description of the procedure or treatment; potential alternative therapies; the option of nontreatment; the underlying disease process and its natural course; the name and qualifications of the health care provider performing the procedure or treatment; explanation of the risks and benefits; explanation that the patient has the right to refuse treatment; explanation that consent can be withdrawn; and explanation of expected (not guaranteed) outcome, recovery, and rehabilitation plan and course.

. **a.** Anticoagulant medications increase the risk for hemorrhage intra- and postoperatively.

. **b.** Adipose (fatty) tissue has poor blood supply, which places the obese patient at risk for delayed wound healing, wound infection, and disruption in the integrity of the wound. Medication interactions are not the primary concern and are managed by the nurse anesthetist or anesthesiologist. Postoperative bleeding and flatulence (gas) after anesthesia are concerns for all patients, not just those with obesity.

. **b.** This patient is displaying typical signs of urinary retention, voiding small frequent amounts. Discomfort is expected and can be managed with prescribed analgesics. Anesthesia or opioid analgesia promotes sedation from which this patient awakens to touch. Dry mouth and thirst can result from NPO status and possible anticholinergic medication intended to dry respiratory secretions during surgery.

. **d.** Written instructions are most effective in providing information for same-day surgery.

. **b.** An open-ended question that allows the patient to express concerns, fears, and feelings is therapeutic and most appropriate. The other options suggest "yes/no" answers or suggest issues that may not be present. This type of communication does not allow the patient to clarify their thoughts.

. **d.** The nurse educates the patient that the PCA pump allows patients to self-administer doses of pain-relieving medication within health care provider–prescribed times and dose limits. It is not realistic to promise absence of pain or unlimited access to medication nor allow the patient to select the pain medication prescribed.

. **a.** A thoracic incision, near or overlying the lungs, makes it difficult or painful for patients to take deep breaths and cough. The nurse uses analgesics, repositioning, coughing and deep breathing, and an incentive spirometer to promote respiratory expansion and airway clearance to decrease the risk for respiratory complications.

. **a, c, d.** Increased wound drainage, restlessness, increasing pulse, and decreasing blood pressure are symptoms of blood loss/hemorrhage and must be promptly identified to prevent shock. Diminished bowel sounds are expected after surgery and anesthesia. Incisional pain is anticipated; the nurse uses prescriptions for analgesia to help resolve pain. Due to NPO status and blood loss from surgery, IV fluids are administered.

. **d.** To prevent DVT, the nurse plans to apply an IPCD and antiembolism stockings. Assessments such as vital signs and calf circumference will detect but not prevent DVT. Maintaining bedrest continues to promote risk, and early ambulation helps prevent DVT.

. **a, b.** The scrub nurse is a member of the sterile team who maintains sterile technique while draping and handling instruments and supplies. Two duties of the circulating nurse are to identify and assess the patient on admission to the OR and prepare the skin at the surgical site. The perioperative registered nurse actively assists the surgeon by providing exposure of the operative area. The advanced practice registered nurse coordinates care activities, collaborates with physicians and nurses in all phases of perioperative and postanesthesia care, and integrates case management, critical paths, and research into care of the surgical patient.

. **b**. Reduced vital capacity in older adults decreases respiratory expansion, increasing the risk for pneumonia and atelectasis. Encouraging the patient to turn, cough, and deep breathe every 4 hours helps to prevent complications.

. **d**. Leg exercises promote venous return and decrease complications related to venous stasis causing DVT and help prevent muscle weakness. These exercises also decrease risk for thrombophlebitis and emboli.

. **16. b.** Patients receiving anticoagulants are at risk for bleeding or hemorrhage during invasive and surgical procedures. Wanting to know an anticipated discharge date is expected, the surgeon can fill out the consent form prior to sedation, and a slight increase in blood pressure is possible related to anxiety before surgery.

UNIT VI Promoting Healthy Physiologic Responses

The art and science of caring are blended when nurses implement actions to meet basic human needs and to promote healthy physiologic responses. The chapters in Unit VI focus on information and guidelines essential to nursing practice in a wide variety of clinical and community settings that involve both healthy and ill patients of all ages. Included are nursing interventions to basic physiologic needs: hygiene, skin integrity, activity and rest, nutrition, elimination, oxygenation, and fluid–electrolyte balance and to promote comfort and pain management.

Each basic physiologic need is discussed first with a review of concepts pertinent to the specific area of human function and response, then with an examination of factors that affect need satisfaction. The steps of the nursing process are used to provide guidelines and information necessary for making accurate assessments establishing outcomes; and planning, implementing, and evaluating specific nursing interventions to meet needs and promote wellness.

The chapters in Unit VI enable the beginning nurse to integrate the knowledge and skills necessary to promote healthy physiologic responses in patients in any practice setting. Nursing process skills are further refined to ensure that care is holistic, comprehensive, and person centered.

“… what nursing has to do is to put the patient in the best condition for nature to act upon him.”

Florence Nightingale (1820–1910), *a philosopher, theorist, statistician, humanitarian, and inspirational leader who founded modern nursing through a systematic method of training well-qualified nurses. She also initiated important reforms in military sanitation and hospital construction that greatly improved patient survival*.

32

Hygiene

Kylie Simpson

Kylie, age 20, is a student at a state university. After having vaginal itching and burning for 2 weeks, she visits the campus health clinic. She is diagnosed with a vaginal infection. She asks the nurse at the campus health clinic, “Is there something wrong with me? This is the second vaginal infection I have had in 7 months. Isn’t there something I can do to keep this from happening again?”

Sonya Delamordo

Sonya is an older Hispanic woman who has had a stroke (brain attack) resulting in right-sided paralysis. She is being discharged from the hospital and will now live with her daughter, who will be her primary caregiver. Her daughter is eager to learn everything she can about caring for her mother and asks numerous questions, including the best way to help her mother with personal hygiene.

Andrew Craig

Andrew, age 68, has multiple diagnoses and limited mobility. He lives in an extended-care facility. Andrew needs assistance with his daily morning care. This morning, however, he tells the nurse, “I’ve

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

already had a complete bath."

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Identify factors affecting personal hygiene.
. Assess the adequacy of hygiene practices and self-care behaviors using appropriate interview and physical assessment skills.
. Assess the condition of the patient's skin, oral cavity, hair, and nails using appropriate interview and physical assessment skills.
. Formulate diagnoses/patient problems related to hygiene amenable to nursing intervention.
. Demonstrate techniques for assisting patients with hygiene measures, including those used when administering various types of baths and those used in cleaning each part of the body.
. Describe agents commonly used on the skin and scalp, including any precautions related to their use.
. Plan, implement, and evaluate nursing care related to diagnoses/patient problems involving alterations in and related to hygiene.

Measures for maintaining a minimal level of personal cleanliness and grooming, called **personal hygiene**, promote physical and psychological well-being. Hygiene practices include bathing and care of the skin and specific body areas, including the oral cavity, eyes, ears, nose, hair, nails, feet, and perineal and vaginal areas. Personal hygiene practices vary widely among people. It is important that personal care be carried out conveniently and frequently enough to promote good hygiene and wellness. Acute and chronic illness, hospitalization, and institutionalization may make it necessary to modify hygiene practices. In these situations, the nurse helps the patient to continue sound hygiene practices and can teach the patient and family members/caregivers, when necessary, regarding hygiene. Nurses assisting patients with basic hygiene must respect individual patient preferences, providing only the care that patients cannot, or should not, provide for themselves. Nurses should value each patient as a person and take into consideration the patient's physical and psychological state of being. Social determinants of health, such as religion and culture, educational perspectives, and financial issues, and their impact on hygiene are important considerations when planning and assisting patients in meeting their hygiene needs (see the accompanying Reflective Practice box on pages 1090) (Moore &

Merrill, 2019; Ramos-Morcillo et al., 2019).

This chapter discusses multiple factors that affect personal hygiene and nursing measures that promote personal hygiene. A practical guide for assessing the adequacy of personal hygiene is presented. The data collected when assisting with hygiene may lead to the identification of multiple diagnoses/patient problems and/or collaborative problems. Examples of such diagnoses/problems are provided in the chapter. In addition, patient outcomes are presented, as are specific nursing strategies used when performing care of the skin, mouth, eyes, ears, nose, hair, nails, feet, perineal areas, and vaginal areas. Nursing considerations related to maintaining an appropriate patient environment are discussed as well. The concluding plan of care related to feminine hygiene illustrates how the nurse uses knowledge of personal hygiene practices and the integumentary system, along with specific nursing interventions, to address diagnoses/patient problems and to promote the patient's general sense of well-being.

HYGIENE PRACTICES

Hygienic practices include caring for the skin, hair, nails, eyes, ears, nose, mouth, feet, and perineal area. There are strong links between good hygiene practices and a person's health. Inadequate hygiene practices can contribute to alterations in a person's health.

The skin, or integument, is the largest organ of the body and has multiple functions. The integumentary system is made up of the skin, the subcutaneous layer directly under the skin, and the appendages of the skin, including the hair and nails. Chapter 33 provides a description of the anatomy and physiology of the integumentary system and factors that affect skin integrity. Adequate skin hygiene, including foot care, contributes to maintaining skin condition and integrity, an important first line of defense, preventing the entry of pathogens, minimizing absorption of harmful substances, and preventing excessive water loss (Lichterfeld et al., 2015; Voegeli, 2019; Wounds UK, 2018).

Hair is an accessory structure of the skin. Good general health is essential for attractive hair and skin, and cleanliness is a positive influence. Illness affects the hair, especially when endocrine abnormalities, increased body temperature, poor nutrition, or anxiety and worry are present. Changes in the color or condition of the hair shaft are related to changes in hormonal activity or to changes in the blood supply to hair follicles.

The nails are an accessory structure of the skin composed of epithelial tissue. Healthy nail beds are pink, convex, and evenly curved. With certain pathologic conditions, and to some extent with aging, the nails become ridged and areas become concave. Hygienic care includes keeping the nails of fingers and feet trimmed and clean.

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO INTERPERSONAL SKILLS

It was our first day of clinical, sophomore year, and we were instructed to provide complete personal care with our patients. My patient, Andrew Craig, was a 68-year-old man with multiple diagnoses and limited mobility. As I entered the room, he told me he had just had a bed bath a few hours earlier. I wasn't sure what to do, so I asked the tech if my patient had already had a complete bed bath. The tech pulled me into the patient's room and proceeded to scream at the patient, telling him not to lie to me and threatening to make him sit in the chair all day. This patient did not have a hip and had antibiotic beads in the area, so it was very painful for him to sit in a chair because the beads dug into his side. The tech then told me to do the bed bath and left the room. I was left in a very awkward position because the patient was mad at me and I was astounded by how the tech had treated this patient. I was extremely upset as a result of this confrontation.

The day was emotionally very difficult for me, and when I arrived home, I became even more upset. The manner in which the tech treated the patient, even though the patient may have been manipulative, was completely out of line.

Thinking Outside the Box: Possible Courses of Action

- Make the best of a bad situation, but do nothing to change the status quo: "Hey, I'm only a student, right?"
- Confront the tech and tell her about my outrage.
- Report the tech to her supervisor.
- Consult with my instructor about how a professional nurse should respond in a situation like this.
- Be prepared to "go to the top" if initial attempts to reform a bad system don't meet with success.

Evaluating a Good Outcome: How Do I Define Success?

- The patient's basic hygiene needs are met.
- The patient's humanity and integrity are respected.
- Health care professionals and technicians are held accountable for incompetent, unethical, and illegal

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

behavior (the tech, nursing leadership, and administration in this long-term care facility).
- I learn how to be a successful patient advocate.

Personal Learning: Here's to the Future!

I proceeded to talk to my clinical instructor and the coordinator of the class about the incident. The coordinator contacted the long-term care facility and I had to give a formal statement about the incident. The nurse manager who took my statement was not very receptive and was actually very patronizing.

This entire experience helped me to recognize the type of nurse I want to be. First and foremost, I always want to ensure that I provide high-quality patient care. At the time of my unfortunate experience, I did not respond immediately to the tech's inappropriate comments. But now that I have gained more experience and become more confident, I would definitely respond immediately if a similar situation ever arose again. I realize that I can't let fear stand in my way when the quality of patient care is suffering. I would encourage any nurse who sees a colleague or anyone treating a patient without the utmost respect and care to speak up and contact appropriate personnel to discuss the situation.

In addition to this tech's inappropriate behavior, the overall conditions of this long-term care facility were appalling. I learned a lot this semester about the shortage of nurses (1 RN for 40 patients) and, consequently, how patient care is being jeopardized. During the unfortunate episode to which I was exposed, I was astonished and outraged, but I didn't take any steps to change the conditions except reporting this one incident. At the end of the semester, we reported the conditions to the class coordinator. Now I realize that as a person, I could have done more to change the conditions in the long-term care facility. In retrospect, I should have taken a leadership role and notified the outside licensing organization about these conditions (the long-term care facility ended up losing its accreditation that summer). All nurses are responsible for ensuring the quality of care given to patients, and we must contact whomever necessary to ensure changes are made.

This experience was very difficult for me, but in the end, I think it opened my eyes to the importance of nurses acting as advocates and leaders.

Catherine Barrell, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve the quality and safety of care for patients like Mr. Craig?

Patient-Centered Care: What factors may have played a role in the tech's actions toward the patient and nursing student? What interventions should the nursing student implement to provide care based on respect for the patient's preferences, values, and needs? How did the nursing student's actions adhere to ethical and legal principles? Did the nursing student act as an advocate for Mr. Craig?

Teamwork and Collaboration/Quality Improvement: How could the nursing staff and other care providers collaborate to provide respectful care for Mr. Craig? What communication skills do you need to improve to ensure you function effectively as a member of the patient care team and to obtain assistance when needed?

Safety/Evidence-Based Practice: Is it within the nursing student's scope of practice to individually contact a higher authority such as a licensing facility about the situation? What evidence in nursing literature provides guidance for decision making regarding providing culturally competent health care?

Informatics: Can you identify the essential information that should be documented in Mr. Craig's electronic record to support safe patient care and coordination of care? Is there other documentation that should be part of the student's response to this incident? Can you think of other ways to respond to or approach the situation?

A person's general health influences the health of that person's mouth and teeth, and proper care of the mouth and teeth contribute to overall health. Maintaining good oral hygiene and dental care has several benefits. There is esthetic value in having a clean and healthy mouth. Having one's own teeth in good condition contributes to an intact body image. In addition, the beginning of the digestive process and tasting pleasure are enhanced when the mouth and teeth are in good condition. Oral health is directly related to systemic health, and poor oral health is associated with diabetes, cardiovascular disease, and metabolic syndrome (American Dental Association, 2019b). Oral health is an important

concern in relation to overall health and quality of life.

The perineal area is dark, warm, and often moist, providing conditions that favor bacterial growth. The patient who cannot clean the perineal area needs the nurse's assistance for this important part of personal hygiene. Neglecting perineal cleaning for the patient who cannot provide self-care often results in physical and psychological discomfort for the patient, skin breakdown, and offensive odors.

FACTORS AFFECTING PERSONAL HYGIENE

Hygiene activities and practices can support health and prevent disease. However, hygiene practices vary widely among groups and people. It is important to respect differences in patient hygiene practices and provide care and information in a nonjudgmental manner. Social determinants of health may influence personal hygiene behaviors.

Culture

It is important to identify cultural variations that could affect a patient's personal hygiene preferences, such as typical bathing habits, and behaviors, such as use of various hygiene-related products (Andrews et al., 2020). For example, people from some cultures place a high value on personal cleanliness and feel unclean unless they shower or bathe at least once daily. Many consider bathing incomplete without the use of products to reduce or mask normal body odors. Other people often find a weekly bath sufficient and may feel no need to mask normal body odors. Culture may also influence whether bathing is a private or communal activity.

Consider **Sonya Delamordo**, the woman being discharged to her daughter's home after experiencing a stroke. Although the daughter is very eager to take care of her mother, the nurse explores the patient's culture to determine how the patient might feel about being cared for by her daughter. Often, hygiene is a personal matter. The nurse needs to discuss hygiene care with the patient and her daughter to ensure person-centered care.

Socioeconomic Status

A person's socioeconomic status and financial resources often define the hygiene options available to that person. A lack of funds to obtain toiletries or clean clothing may contribute to an inability to maintain personal hygiene needs. For example, someone renting a room in a boarding house may have limited or no access to a tub or shower and may have limited finances to buy soap, shampoo, shaving cream, and deodorant. People who are homeless, who often carry all their belongings in a car or shopping cart, may welcome the warm running water and soap available in roadside or public restrooms.

Spiritual Practices

Spiritual practices, including religious beliefs, may dictate ceremonial washings and purifications, sometimes as a prelude to prayer or eating. For example, in the Orthodox Jewish tradition, ritual baths are required for women after childbirth and menstruation. In some religions, contact with a deceased person or a deceased animal may make a person "unclean." Other religions dictate that no modern facilities be installed in homes. This would prohibit some people from having running water and toilets in their homes. As a result, they may bathe infrequently.

Developmental Level

Children learn hygiene practices while growing up. Family practices often dictate hygiene habits, such as morning or evening baths; the frequency of shampooing, tooth brushing, and clothing changes; feelings about nudity; and so on. As adolescents become more concerned about their personal appearance, they may adopt new hygiene measures, such as taking showers more frequently and wearing deodorant. Bathing frequency commonly decreases as a person ages, possibly due to limitations in mobility and the natural tendency toward drier skin with age. Older adults may experience an increase in skin conditions or problems, increasing the need for education related to hygiene and skin care (Lichterfeld-Kottner et al., 2020; Moore & Merrill, 2019).

Health State

Disease, surgery, or injury may reduce a person's ability to perform hygiene measures or motivation to follow usual hygiene habits. Weakness, dizziness, and fear of falling may prevent a person from entering a tub or shower or from bending to wash the lower extremities. Illness may also create a demand for new or modified hygiene measures. For

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

example, meticulous foot care becomes a priority for patients with peripheral vascular complications that often accompany diabetes mellitus. The presence of pain with an acute condition or chronic pain can affect a person's ability to perform and/or tolerate personal hygiene measures.

Remember **Sonya Delamordo**, who has right-sided paralysis as a result of a stroke. She will have to adapt to caring for herself, dealing with the mobility limitations of her right side, especially if she is right handed. Both she and her daughter will have to learn how to adapt personal hygiene practices based on Sonya's abilities.

Personal Preferences

People have different preferences with regard to hygiene practices such as taking a shower versus a tub bath, using bar soap versus liquid soap, and washing to wake oneself or to relax before sleep. A person's self-concept and sexuality also influence personal hygiene practices. For example, in an effort to promote a positive self-image, older adults may use skin care products advertised to prevent wrinkles and diminish signs of aging. Women who are sexually active may use a variety of hygiene products following intercourse to promote cleanliness.

NURSING PROCESS FOR PERSONAL HYGIENE AND SKIN CARE

Assessing

The comprehensive nursing assessment uses interview and assessment skills to elicit data about the patient's hygiene status. When alterations in a patient's physical or mental health result in impaired ability to maintain acceptable personal hygiene, additional specific assessment skills are needed to determine the patient's limitations.

Nursing History

Bathing practices and cleansing habits and rituals vary widely. A clear threat to health must exist before a nurse decides that a person's hygiene practices are inadequate. The nurse assessing the adequacy of a patient's hygiene practices determines whether the patient has the knowledge, attitude, skills, and resources to care for the skin and mucous membranes. Use neutral and inclusive terms (e.g., partner) and a nonjudgmental manner to obtain information about the patient's gender identity, biologic sex, and sexual orientation. This information will help identify the needs of individual patients and provide thoughtful, person-centered care (Altarum Institute, 2019; Cahill et al., 2020). Focused Assessment Guide 32-1 provides additional suggested strategies, questions and approaches for an assessment of information related to hygiene practices. When documenting the nursing history, be specific, clearly describing the patient's typical hygiene practices and any issues or problems.

SKIN

Question the patient about any past or current skin problems and changes in their skin (e.g., rashes, lumps, itching, dryness, lesions) as well as recent surgeries, wounds, tattoos, or piercings. When skin problems are present, ask the patient the following:

- How long have you had this problem?
- Does it bother you?
- How does it bother you?
- Does it itch?
- Have you found anything that helps relieve these symptoms?

Additional information related to assessment of the skin is discussed in Chapter 27 and Chapter 33.

ORAL CAVITY

Identify the patient's normal oral hygiene practices and the variables influencing these practices. Note the history of any oral problems and related treatments.

Identify any variables known to cause oral problems, such as deficient self-care abilities, poor nutrition or excessive intake of refined sugars, family history of periodontal disease, or ingestion of chemotherapeutic agents that produce oral lesions. Patients at increased risk for oral problems include those who are seriously ill, comatose,

dehydrated, confused, depressed, or paralyzed. Patients with mental health problems are also at risk for alterations in oral health (Griffiths et al., 2020; Kisely, 2016). Patients who are mouth breathers, those who can have no oral intake of nutrition or fluids, those with nasogastric tubes or oral airways in place, and those who have had oral surgery are also at increased risk.

Additional information related to assessment of the oral cavity is discussed in Chapter 27.

EYES, EARS, AND NOSE

Ask the patient to identify any special eye, ear, or nose care that the patient performs. Also, address any specific care measures related to the use and care of visual aids or prosthetics (glasses, contact lenses, artificial eye) and hearing aids. Inquire about any history of eye, ear, and nose problems, and related treatments.

Additional information related to assessment of the eyes, ears, and nose is discussed in Chapter 27.

Focused Assessment Guide 32-1

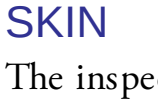
HYGIENE PRACTICES

Factors to Assess	Questions and Approaches
Daily and weekly bathing habits	Tell me about your daily and weekly bathing habits. Are there special bathing or hygiene products you routinely use or can't use? How can the nursing staff best help you to meet your hygiene needs?
Factors interfering with hygiene practices (sensory, cognitive, endurance, mobility, or motivation)	What recently or in the past has interfered with your hygiene practices? Does anything interfere with your ability to be as clean as you would like?
Pain	Do you have pain? Describe characteristics, onset, location, duration, associated symptoms, and intensity. Does the pain interfere with your ability to perform personal hygiene tasks? Does caring for yourself cause pain or discomfort?
Exposure history	Do you sunbathe? How much sun or tanning booth exposure do you get? Do you use sunscreen? Does your job or daily activities/hobbies expose you to chemicals, such as bleach, petroleum, paint, insecticides, or cleaning products?
History of skin or mucous membrane problems (nature, onset of problem and frequency, causes, severity, symptoms, interventions attempted, results)	Have you noticed any changes in your skin or mucous membranes? Describe any skin problems with rashes, lumps, itching, dryness, lesions, ecchymosis, or masses. What have you used to relieve these symptoms?
Special hygiene practices	
• Mouth	How do you clean your teeth and gums? How often do you have a dental examination? Do you have any dental appliances? Are there any tender areas or lesions in your mouth?
• Eyes, ears, and nose	Do you wear glasses or contact lenses to improve your vision? Do you wear a hearing aid? Have you noticed any changes in your eyes, ears, or nose? Have you experienced any discharge or bleeding from or swelling of your eyes, ears, or nose?
• Hair	Have you noticed any changes in your hair? Have you noticed any unusual dryness of the scalp or changes in hair texture and amount?
• Feet and nails	Have you noticed any changes in your feet or nails? Is the appearance of the nails normal? How do you normally care for and clean your nails? Is the skin intact on the feet? Have you noticed any swelling of one or both feet? Do you wear any special shoes?
• Perineum	Have you noticed any changes in your perineum? Have you noticed any unusual discharge, swelling, itching, or inflammation? Are you able to complete your own perineal care? Do you follow any special hygiene practices during menstruation? What type of feminine hygiene products (e.g., pads, tampons, douches) do you use?
• Piercings/Tattoos	Do you have any body piercings on your face, neck, arms, legs, torso, navel, or genitals? Have you experienced any problems related to the procedure? Do you have any tattoos? Are the tattoos healed? How do you care for your piercing(s) and/or tattoo(s)?

HAIR

Identify the patient's usual hair and scalp care practices, including styling preferences. Note any history of hair or scalp problems; possible causes of changes in the distribution, texture, or amount of hair; and related treatments. Be alert for any factors that are known to cause hair or scalp problems or that require special care such as deficient self-care abilities, immobility, malnutrition, and treatments known to result in hair loss (e.g., certain chemotherapeutic agents).

Additional information related to assessment of the hair is discussed in Chapter 27.



for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

NAILS AND FEET

Gather information about the patient's normal nail and foot care practices. Include the type of footwear worn and any history of nail or foot problems and their treatments. Foot problems, particularly common in people with diabetes mellitus and peripheral vascular disease, often require hospitalization. A proactive educational approach can prevent many of the serious complications (e.g., ulcers, lower extremity amputations) associated with foot problems.

Identify any variables known to cause nail and foot problems, such as deficient self-care abilities, vascular disease, arthritis, diabetes mellitus, history of biting nails or trimming them improperly, frequent or prolonged exposure to chemicals or water, trauma, ill-fitting shoes, or obesity.

Additional information related to assessment of the nails and feet is discussed in Chapter 27.

Concept Mastery Alert

Diabetes mellitus can result in peripheral vascular disease; patients who have peripheral vascular disease may require hospitalization related to problems associated with the feet.

PERINEAL AND VAGINAL AREAS

Note any history of perineal or vaginal problems and related treatments. Identify any variables known to cause perineal or vaginal problems or to create a need for special care, such as urinary or fecal incontinence, an indwelling Foley catheter, childbirth, douching, rectal or genital surgery, and diseases such as urinary tract infection, diabetes mellitus, and certain sexually transmitted infections (STIs; e.g., herpes).

Additional information related to assessment of the perineal area is discussed in Chapter 27.

Physical Assessment

An assessment of pertinent body systems can provide data about the patient's hygiene status and the patient's ability to maintain personal hygiene.

MUSCULOSKELETAL SYSTEM

Impairment of the musculoskeletal system can interfere with a patient's ability to perform tasks related to personal hygiene. Many conditions produce muscle weakness, decreased range of motion, impaired balance, fatigue, and/or lack of coordination. The skills used to assess the musculoskeletal system are described in detail in Chapters 27 and 34.

SKIN

The inspection and palpation skills used to assess the integumentary system are described in detail in Chapters 27 and 33. Assisting patients with basic hygiene measures provides an excellent opportunity for examining a patient's skin. Many people are unaware that they have skin lesions, such as precancerous moles, that if untreated could prove fatal. Early detection and treatment of skin problems are important nursing functions.

When examining the skin, pay careful attention to cleanliness, color, texture, temperature, turgor, moisture, sensation, vascularity, and any lesions. Follow these general guidelines for assessing the skin:

- Incorporate assessment of the skin during the assessment of other body systems.
- Use a good source of light, preferably daylight.
- Compare bilateral parts for symmetry.
- Use standard terminology to communicate and record findings.
- Allow data obtained in the nursing history to direct the skin assessment.
- Identify any variables known to cause skin problems, such as deficient self-care abilities, immobility, malnutrition, decreased hydration, decreased sensation, sun exposure, vascular problems (altered tissue perfusion or venous return), or the presence of irritants (body secretions or excretions on the skin, other chemicals, mechanical devices).

Because lifestyle factors, changes in health state, illness, and certain diagnostic and therapeutic measures may adversely affect the skin, be alert for patients who may be at high risk for skin problems, and perform the appropriate skin assessment. Assessment may reveal dry skin, acne, or skin rashes. Recommended treatments for these skin problems are discussed in the Promoting Skin Health section on page 1102.

When documenting a physical assessment of the skin, describe exactly what is observed or palpated, including appearance, texture, size, location or distribution, and characteristics of any findings.

ORAL CAVITY

A physical assessment of the oral cavity involves inspection of the oral cavity and surrounding structures with attention to any unusual odors. When performing the physical assessment of the oral cavity, examine the following:

- *Lips:* color, moisture, lumps, ulcers, lesions, and edema
- *Buccal mucosa:* color, moisture, lesions, nodules, and bleeding
- *Color of the gums and surface of the gums:* lesions, bleeding, and edema
- *Teeth:* any loose, missing, or carious (decayed) teeth. Note the presence and condition of dentures or other orthodontic devices
- *Tongue:* color, symmetry, movement, texture, and lesions
- *Hard and soft palates:* intactness, color, patches, lesions, and petechiae (pinpoint round, red, purple, or brown spots that result from bleeding)
- *Oropharynx:* movement of the uvula and condition of tonsils, if present

Note unusual mouth odors and assess the adequacy of mastication and swallowing. An oral assessment tool can assist with assessment of the status of the oral cavity, as well as help to determine the frequency and procedure for oral care (Chick & Wynne, 2020). Identifying the problem and its cause and initiating appropriate treatment are imperative. This may require consultation with a dentist or health care provider. Refer to Chapter 27 for further description of nursing assessment of the oral cavity.

Dental Caries

The decay of teeth with the formation of cavities is called **caries**. Caries result from failure to remove **plaque**, an invisible, destructive, bacterial film that builds up on everyone's teeth and eventually leads to the destruction of tooth enamel. A successful plaque-fighting program includes limiting sweet snacks such as soft drinks, candy, gum, jams, and jellies between meals; thorough cleansing of the teeth; and regular dental checkups. The use of antiplaque fluoride toothpastes, mouth rinses, and flossing also help prevent dental caries.

Periodontal Disease

Periodontal diseases are the result of infections and inflammation of the gums and bone that surround and support the teeth (CDC, 2013). Periodontal disease and tooth decay are the two biggest threats to dental health (CDC, 2013). **Gingivitis** is an inflammation of the gingiva, the tissue that surrounds the teeth. **Periodontitis**, or periodontal disease, is a marked inflammation of the gums that also involves degeneration of the dental periosteum (tissues) and bone. Symptoms include bleeding gums; swollen, red, painful gum tissues; receding gum lines with the formation of pockets between the teeth and gums; pus that appears when gums are pressed; and loose teeth. If unchecked, plaque builds up and, along with dead bacteria, forms hard deposits called **tartar** at the gum lines. The tartar attacks the fibers that fasten teeth to the gums and eventually attacks bone tissue. The teeth then loosen and fall out. **Halitosis**, a strong mouth odor or a persistent bad taste in the mouth, may be the first indication of periodontal disease. Regular treatment by a dentist is imperative.

Other Oral Problems

Other oral problems that may be observed when inspecting the oral cavity include the following:

- **Stomatitis**, an inflammation of the oral mucosa, has numerous causes, such as bacteria, virus, mechanical trauma, irritants, nutritional deficiencies, and systemic infection. Symptoms may include heat, pain, increased flow of saliva, and halitosis.
- **Glossitis**, an inflammation of the tongue, can be caused by deficiencies of vitamin B_{12}, folic acid, and iron.
- **Cheilosis**, an ulceration and dry scaling of the lips with fissures at the angles of the mouth, can have multiple causes, including infections of the oral cavity (e.g., strep bacteria), a lack of iron or B vitamin deficiencies (especially riboflavin), and skin irritation (e.g., eczema).
- Dry oral mucosa may simply be related to dehydration or may be caused by mouth breathing, an alteration in salivary functioning, or certain medications (e.g., anticholinergic drugs).
- Oral malignancies, appearing as lumps or ulcers, must be distinguished from benign mouth problems because early detection may lead to cure; later detection can lead to radical surgery or death. Teach patients to see their dentist immediately if they notice white or red patches, persistent sores, swelling, bleeding, numbness, or pain in the mouth.

EYES, EARS, AND NOSE

During the eye examination, note the position, alignment, and general appearance of the eye. Check that eyelashes are distributed equally and curl outward. Note the presence of lesions, nodules, redness, swelling, crusting, flaking, excessive tearing, or discharge of eyelids. Check the color of the conjunctivae.

When examining the ear, note its position, alignment, and general appearance. Pay particular attention to a buildup of **cerumen** (wax) in the canal, dryness, crusting, or the presence of any discharge or foreign body. Older adults can have a buildup of cerumen that can cause impaired hearing. This is a result of harder, drier cerumen and decreased motility of the cilia in the ear canal.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

While examining the nose, note its position and general appearance, patency of the nostrils, and presence of tenderness, dryness, edema, bleeding, discharge, or secretions.

Refer to Chapter 27 for additional information related to nursing assessment of the eyes, ears, and nose.

HAIR

Assess the condition of the hair. Inspect it for texture, cleanliness, and oiliness. Inspect the scalp for any scaling, lesions, inflammation, or infection. Note any abnormalities such as dandruff, hair loss, or infestations. Patients of African American descent may have very dry scalps and dry, fragile hair (Andrews et al., 2020). Patients of Asian descent may have straight hair that does not necessarily require special care (Andrews et al., 2020). When in doubt, ask the patient, a family member, or significant other about the specific manner in which hair care is performed. Refer to Chapter 27 for additional information related to nursing assessment of hair.

Dandruff

Dandruff is a condition characterized by itching and flaking of the scalp and may be complicated by the embarrassment it causes. Persistent, severe cases usually require medical attention, but daily brushing and shampooing with a medicated shampoo may be all that is needed to keep the scalp free of dandruff.

Hair Loss

Hair growth and hair loss are ongoing, daily processes. Hair loss becomes a potential problem only when it exceeds hair growth. Absence or loss of hair is called **alopecia**. Alopecia on the head is also referred to as baldness. Alopecia can be a partial or complete, local or generalized, loss of hair. Patchy hair loss can result from infections of the scalp. Hair loss from plaiting, excessive backcombing and teasing, or the use of hair rollers is usually temporary; hair returns when the tension on the hair shaft is halted.

Excessive generalized hair loss may occur with infection, nutritional deficiencies, hormonal disorders, childbirth, general anesthesia, drug toxicity, chemotherapy, thyroid disease, liver disease, hepatic and renal failure, and radiation. Alopecia can also occur as part of the aging process. Alopecia related to aging is more common in men than in women. There is no known cure for baldness. Although some medications are currently in use and others are being developed, their long-term efficacy is unknown. For example, minoxidil, a cardiovascular and antihypertensive drug, has reversed balding to some degree when applied to the scalp. Hairpieces, sometimes worn by people who are bald, require the same care as normal hair but less frequent washing.

Hair transplantation is a surgical procedure for baldness. Hair is taken from donor sites, usually from the back or sides of the scalp, and transplanted to areas with no hair. The procedure is long and expensive but reportedly has decided benefits for people who find baldness psychologically unpleasant. Complications include serious scalp infections.

Pediculosis

Infestation with lice is called **pediculosis**. There are three common types of lice: *Pediculus humanus capitis,* which infests the hair and scalp; *Pediculus humanus corporis,* which infests the body; and *Phthirus pubis,* which infests the shorter hairs on the body, usually the pubic and axillary hair. Lice lay eggs, called nits, on the hair shafts. Nits are white or light gray and look like dandruff but cannot be brushed or shaken off the hair. Frequent scratching and scratch marks on the body and the scalp suggest the presence of pediculosis. Pediculosis can be spread directly by contact with the hair of infested people. It is less common for transmission to occur indirectly through contact with clothing, bed linen, brushes, and combs of infested people. Treatment for pediculosis is discussed in the Providing Hair Care discussion on page 1111.

NAILS AND FEET

Examine nails for intactness and cleanliness. Assess capillary refill and the contour of the nail bed. Observe the nail base for redness, swelling, bleeding, discharge, and tenderness. Patients with dark skin tones may have freckles or pigmented streaks in their nails and nails may be thicker (Jarvis & Eckhardt, 2020). Examine the feet for cleanliness and intactness of skin, and note any swelling, inflammation, lesions, tenderness, or orthopedic problems. Carefully examine the skin between the toes. Refer to Chapter 27 for additional information related to nursing assessment of the nails and feet.

PERINEAL AND VAGINAL AREAS

Examine the male genitalia for color, lesions, swelling, inflammation, excoriation, tenderness, and discharge (amount, color, odor, source). Examine the female genitalia for color, lesions, masses, swelling, inflammation, excoriation, tenderness, and discharge (amount, color, odor, source). Inspect the anal area for cracks, nodules, distended veins, masses, or polyps. Note any perineal odors. Refer to Chapter 27 for additional information related to nursing assessment of the perineum.

Diagnosing Actual or Potential Health Problems and Needs

An assessment of a patient's hygiene practices and the skin, mucous membranes, and other body areas may lead to the identification of one or more diagnoses or patient problems related to hygiene. Following the formulation of the diagnoses or patient problems, the nurse communicates findings to other nursing and health care professionals through the use of the written and spoken word. The written diagnosis or patient problem becomes a permanent part of the patient's health record. Examples of health problems and needs with related etiology and signs and symptoms can be found in the box titled Examples of Actual or Potential Health Problems and Needs: Hygiene.

Examples of Actual or Potential Health Problems and Needs

HYGIENE

Actual or Potential Health Problems and Needs	Possible Etiologic Factors	Potential Signs and Symptoms
Bathing/hygiene ADL deficit	Sensory, cognitive, endurance, mobility, or motivation deficits; low value attached to regular bathing, brushing, flossing, and dental examinations; pain	"I don't need a bath. I'm not dirty." Five days postoperative from left thoracotomy. Transient confusion, generalized postoperative weakness. Unable to ambulate more than a few steps with assistance of two caregivers.
Impaired socialization	Negative body image	"I hate the way I look. Everyone stares at me. I don't even feel like going to school." Sixteen-year-old boy has come to the pediatrician's office for a physical for his driver's license permit. He has severe acne involving his face, neck, and back.
Risk for Impaired Oral Mucous Membrane Integrity	Inadequate oral hygiene, immunosuppression, inadequate nutrition, dehydration	—

Source: International Council of Nurses (ICN). (2019). *Nursing diagnosis and outcome statements*. https://www.icn.ch/sites/default/files/inline-files/ICNP2019-DC.pdf; Wolters Kluwer. (2020). Problem-based care plans. In Lippincott Advisor. Wolters Kluwer. https://advisor.lww.com/lna/home.do

Outcome Identification and Planning

The plan of care identifies nursing measures to assist the patient to develop or maintain hygiene practices that contribute to a sense of well-being. The following are examples of appropriate outcomes. The patient will:

- verbalize feeling comfortable and clean.
- participate fully in necessary hygiene measures according to cognitive, sensory, mobility, and endurance abilities.
- maintain intact skin and mucous membranes.
- demonstrate correct skin care measures (when indicated) such as oral care; care of eyes, ears, and nose; nail and foot care; and perineal and vaginal care.
- verbalize importance of good teeth-brushing habits, fluoride use, and regular dental examinations.
- demonstrate proper use and care of visual or auditory aids.
- participate in hair and scalp care as able.

Implementing

When performing general hygiene measures, respect the patient's personal preferences and encourage as much self-care as the patient can perform. Nurses should implement interventions to meet the patient's need for privacy, and promote physiologic and psychological wellness.

QSEN PATIENT-CENTERED CARE

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Cultural, ethnic, family, and social backgrounds contribute to a patient's values regarding personal hygiene measures. Individualized care respects and encourages individual expression of patient values, preferences, and needs.

The following sections discuss hygiene measures, including providing scheduled care; assisting with bathing and skin care; massaging; providing routine hygiene care; providing environmental care, including making the bed; and teaching patients about skin care. Refer to the accompanying Focus on the Older Adult display for interventions related to hygiene for this age group.

Nurses who role model good health behaviors are more effective teachers. Use the Promoting Health 32-1 (on page 1098) display for yourself before using it with others.

Providing Scheduled Hygiene Care

When patients require nursing assistance with personal hygiene, provide this care at regular intervals. In most hospitals and long-term care settings, early morning care, morning care, afternoon care, hour of sleep care, and care as needed are provided. These are individualized according to the patient's personal and cultural preferences. Personal care assistance in the home and other community-based settings centers on patient preferences and routines. Personal care measures may be delegated to assistive personnel (AP). The nurse is responsible for ensuring that hygiene measures are performed satisfactorily and validates, analyzes, documents, communicates, and acts on any items noticed during care and communicated by AP.

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES IN HYGIENE

Age-Related Changes	Nursing Strategies
Impaired Oral Mucous Membrane	
• Loss of elasticity, atrophy of epithelial cells, diminished blood supply to connective tissue • Decreased salivation • Use of medications for chronic conditions that may cause dry mouth	• Floss and brush teeth with fluoride toothpaste twice a day; rinse after meals. • Brush dentures twice a day and rinse with cool water; remove and rinse dentures and rinse mouth after meals. • Avoid mouthwashes with alcohol content. • Inspect mouth daily for lesions and inflammation. • Use lubricant on lips. • Suck on sugar-free candies, chew sugarless gum, use salivary substitutes. • Continue with dental exams at the dentist every 6 months.
Impaired Physical Mobility	
• Decreased range of motion • Presence of chronic conditions that compromise functional ability • Decreased muscle strength and agility	• Use adaptive devices for hygiene such as toothbrush with a large or extended handle, long-handled body sponge, shower chair, and grab bars. • Provide for safety in the bathroom: use nonslip mats, grab bars.
Risk for Impaired Skin Integrity	
• Diminished secretion of natural oils and perspiration • Loss of elasticity • Thinning of epidermis, loss of elastin and subcutaneous fat	• Use safe water temperatures to bathe; warm water, not hot. • Avoid soap; use pH-balanced skin cleansers. • Shower instead of tub bath. • Use skin moisturizers and emollients at least daily. • Bath regularly, but less often (not every day).

Promoting Health 32-1

HYGIENE

Use the assessment checklist to determine how well you are meeting your needs related to hygiene. Then develop a prescription for self-care by choosing appropriate behaviors from the list of suggestions.

Assessment Checklist

☐ almost always ☐ sometimes ☐ almost never

☐ ☐ ☐ 1. I keep my hair clean and neatly styled.

☐ ☐ ☐ 2. My skin is clean.

☐ ☐ ☐ 3. The condition of my mouth indicates satisfactory oral hygiene.

☐ ☐ ☐ 4. My nails are neatly manicured.

☐ ☐ ☐ 5. My body is free of unpleasant odors.

Self-Care Behaviors

1. Ensure that diet and exercise are appropriate, since this contributes to healthy skin.
2. Brush and floss teeth regularly and visit the dentist every 6 months.
3. Keep hair clean, combed, and brushed regularly.
4. Use certain hair care products (e.g., hair dyes) cautiously, since they may damage the hair.
5. Clean under nails and maintain nails at an appropriate length. Clip all nails straight across and shape or smooth with an emery board or file, if necessary.
6. Bathe and cleanse skin regularly. Apply lotion or cream to dry skin, as necessary. Cleanse the axilla and perineal area thoroughly and apply deodorant or antiperspirant as needed.
7. Appreciate the relationship between hygiene and overall well-being.

Information to promote healthy hygiene practices is available online.

Remember **Andrew Craig**, the older man in the extended-care facility who reported that he had already had a complete bath. The nurse would need to investigate this to determine if he had indeed received care. If he had not, then the nurse would need to seek additional information to explain his statement; perhaps the patient was too tired or did not like having to be helped with his care. This information contributes to providing person-centered care.

EARLY MORNING CARE

Shortly after the patient awakens, assist with toileting if necessary and then provide comfort measures to refresh the patient and prepare them for breakfast (or diagnostic tests, procedures, or therapies). Nursing measures include washing the face and hands and providing mouth care.

MORNING CARE (AM CARE)

In many care environments, it is usual to complete morning care after breakfast. However, patient preferences and scheduled activities should be considered. For example, in rehabilitation settings, patients participate in physical and occupational therapy sessions for a majority of the daytime hours and patient bathing and other personal hygiene measures will be addressed in the evening.

Depending on the patient's self-care abilities, offer assistance with toileting, oral care, bathing, back massage, special skin care measures (e.g., pressure injury), hair care (includes shaving if indicated), cosmetics, dressing, and positioning for comfort. Facility policies are followed for refreshing or changing bed linens, and the patient's bedside area is tidied. In the home and other community-based settings, patient and/or family preferences and routines should be considered. When morning care is completed, the patient should feel refreshed and should be in a comfortable and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

safe environment.

Morning care is often categorized as self-care, partial care, or complete care. Patients identified as self-care are capable of managing their personal hygiene independently once oriented to the bathroom. However, offer a back massage and spend time assessing the patient's day-to-day needs. Patients identified as partial care often receive morning hygiene care at the bedside or seated near the sink in the bathroom. They usually require assistance with body areas that are difficult to reach. Patients identified as complete care require nursing assistance with all aspects of personal hygiene. A complete bed bath is done, or the patient may be taken to the shower.

AFTERNOON CARE (PM CARE)

Hospitalized patients frequently receive visitors in the afternoon or evening or use this time to rest when not scheduled for tests or therapies. Ensure the patient's comfort after lunch and offer assistance to nonambulatory patients with toileting, handwashing, and oral care. Bathing and other personal care activities may take place at this time, depending on individual patient circumstances.

HOUR OF SLEEP CARE (HS CARE)

In the evening, at the end of the day, again offer assistance with toileting, washing of the face and hands, and oral care. It may be appropriate to offer a back massage or other method of relaxation to help the patient to be calm and fall asleep. Change any soiled bed linens or clothing, and position the patient comfortably. Ensure that the call light and any other objects the patient desires (e.g., urinal, radio, water glass) are within easy reach.

AS NEEDED CARE (PRN CARE)

In addition to scheduled care, offer individual hygiene measures as needed. Some patients require oral care every 2 hours. Patients who are diaphoretic (sweating profusely) may need their clothing and bed linens changed several times a shift. At other times, a nurse may decide to forego hygiene measures because the patient's need for undisturbed rest may be a higher priority.

Assisting With Bathing and Skin Care

Bathing serves a variety of purposes, including:

- Cleansing the skin
- Acting as a skin conditioner
- Helping a person to relax
- Promoting circulation by stimulating the skin's peripheral nerve endings and underlying tissues
- Serving as a musculoskeletal exercise through activity involved with bathing, thereby improving joint mobility and muscle tonus
- Stimulating the rate and depth of respirations
- Promoting comfort through muscle relaxation and skin stimulation
- Providing sensory input
- Helping to improve self-image
- Providing an excellent opportunity to strengthen the nurse–patient relationship, to thoroughly assess the patient's integumentary system, to observe the patient's physiologic and emotional status closely, to teach the patient as indicated, and to demonstrate care and interest in the patient's general welfare

The simple act of bathing a patient is a vital and caring intervention. Although APs are increasingly performing hygiene measures, the nurse is responsible for ensuring that hygiene measures are performed satisfactorily. Refer to Chapters 10 and 17 for discussions of the nurse's accountability when care is delegated. Nurses whose primary focus is the patient, however, can use the time spent on assisting with bathing to establish a rapport with the patient and to further assess the patient's integumentary system. Bathing is performed in a matter-of-fact and dignified manner. Refer to the accompanying Through the Eyes of a Student.

SHOWER AND TUB BATHS

A shower may be the preferred method of bathing for patients who are ambulatory and able to tolerate the activity. Tub baths may be an option, particularly in long-term care or other community-based settings, depending on facility policy as well as in a patient's home environment. Tub, or immersion, bathing may be used for purposes other than personal hygiene. Tub bathing can provide positive physical and mental effects, including mental and physical relaxation, decreased stress, and relief of menstrual cramps and labor contractions (Benfield et al., 2018; Goto et al., 2018). For the most part, even though many patients can bathe on their own, the following responsibilities apply:

Through the Eyes of a Student

I entered the room with a feeling of dread. How could I possibly bathe the sick, older adult, helpless woman lying in this hospital bed? I had never bathed anyone older than age 2 years, other than myself, of course. How would I be able to move her limp, seemingly lifeless old body? What would an 85-year-old body look like? I could not imagine. I've read all the manuals that describe this procedure, I know what to do; so why am I so nervous? I must be worried that I will hurt her in some way. Maybe she has not been cared for properly before and her hygiene is poor. Well, I might as well get this over with because I'll be doing it the rest of my life. I've got to learn sometime.

I've mustered up enough courage to enter my patient's room. Michelle, her primary nurse, offers to help me because the patient is so difficult to move. Boy, am I relieved! Right before Michelle and I are about to begin, my patient, Mrs. Ash, asks for her teeth. I assume this must mean her dentures and reassure her that I have not seen them but will be happy to look for them as soon as we have completed her bath. Michelle and I each take a side and begin to bathe her. It's truly amazing how those range-of-motion exercises come to mind so easily. I had thought they were long forgotten with the rest of the past semester. Wouldn't my instructors love to hear me now! Suddenly Mrs. Ash yells, "I need the bedpan!" "Oh no!" I thought, as I rushed to the bathroom with soapy gloved hands trying frantically to locate her bedpan before there could be an accident. Michelle, who remained calm during my frenzy, simply stated, "Don't worry, she has an indwelling catheter. She says that every time I bathe her." I knew she had a catheter, how did I forget? Somewhat humbled, I returned to the procedure. I really wanted to put some lotion on her skin because it was so dry. When we were ready to do her back, we prepared to lift her. I pulled her toward me, and Michelle was to continue the bath. We were not prepared for what we saw underneath. Firmly cushioned in Mrs. Ash's lower left buttock were none other than her dentures! On removing them, Michelle and I had to smile at the periodontal grin implanted on Mrs. Ash's bottom. Michelle then asked her how her teeth had gotten to the location where we found them. All she seemed to know was that she needed those teeth back in her mouth NOW! She snatched the dentures from Michelle's hand and attempted to insert them. Michelle and I in unison blurted out, "No, Mrs. Ash, please wait until we clean your teeth before you put them back in your mouth!" Mrs. Ash, somewhat confused, begrudgingly handed over her teeth to be cleaned. Michelle had the honors while I finished the last touches of good hygiene for Mrs. Ash.

What a difference cleanliness can make, not only for the patient, but also for me, the student nurse. I felt better knowing that Mrs. Ash was clean and that this procedure was behind me. And to think that I was apprehensive! This was definitely an interesting learning experience.

—Marilyn Johnson, Holy Family College, Philadelphia

Box 32-1 Meeting the Bathing Needs of Patients With Dementia

- Shift the focus of the interaction from the "task of bathing" to the needs and abilities of the patient. Focus on comfort, safety, autonomy, and self-esteem, in addition to cleanliness.
- Individualize patient care. Consult the patient, the patient's record, family members, and other caregivers to determine patient preferences.
- Consider what can be learned from the behaviors associated with dementia about the needs and preferences of the patient. A patient's behavior may be an expression of unmet needs; unwillingness to participate may be a response to uncomfortable water temperatures or levels of sound or light in the room.
- Ensure privacy and warmth.
- Consider the use of music to soothe anxiety and agitation.
- Consider other methods for bathing. Showers and tub baths are not the only options in bathing. Towel baths, washing under clothes, and bathing "body sections" one day at a time are other possible options.
- Maintain a relaxed demeanor. Use calming language. Use one-step commands. Try to determine phrases and terms the patient understands in relation to bathing and make use of them. Offer frequent reassurance.
- Encourage independence. Use hand-over-hand or a guided hand technique to cue the patient regarding the purpose of the interaction and allow the patient to perform some of the activities independently.
- Explore the need for routine analgesia before bathing. Move limbs carefully and be aware of signs of discomfort during bathing.
- Wash the face and hair at the end of the bath or at a separate time. Water dripping in the face and having a wet head are often the most upsetting parts of the bathing process for people with dementia.

2180; and Toughy, T. A., & Jett, K. (2018). *Ebersol and Hess' gerontological nursing & healthy aging* (5th ed.). Elsevier.

- Check to see that the bathroom is available, clean, and safe. Showers should have mats or nonskid strips to prevent patients from slipping and falling.
- Ensure that necessary articles—such as skin cleanser, washcloth, towel, and gown—are available for the patient.
- Provide a place for a weak or physically disabled patient to sit in a shower. Most health facilities have a stool or chair that can be used in the shower, and handheld showerheads may facilitate the process. A commode chair with the pan removed serves effectively as a shower chair and may offer the patient more support than a stool or chair.
- Assist the patient to the shower or bathroom, as indicated. Patients who are beginning ambulation often need assistance to help prevent falling or fainting.
- Check to see that the water temperature is safe and comfortable—no more than 120°F. Use a thermometer to test the water coming out of the bath water tap (International Association of Fire Fighters [IAFF], n.d.).
- Ensure privacy for patients who can safely shower or bathe independently. See that a call device is handy, and make sure the patient knows what the button is for so the patient can obtain help if necessary.
- Help the patient get in and out of the bathtub, as indicated. Have the patient grasp the handrails at the side of the tub, or place a chair at the side of the tub. The patient sits on the chair and eases to the edge of the tub. After putting both feet into the tub, it is then relatively easy for the patient to reach the opposite side and ease down into the tub. The patient may kneel first in the tub and then sit in it; this process can be reversed when leaving the tub. Use a hydraulic lift, when available, to lower and lift patients who are unable to maneuver safely or completely bear their weight. Some community-based settings or homes have walk-in tubs available.
- Keep the bathroom door unlocked. Health personnel should be able to enter with ease if the patient needs help. A sign hung on the door ensures privacy. Never leave children or confused patients alone in the bathroom.
- Help to wash and dry areas of the body that the patient cannot reach, such as the back.
- Make any necessary adaptations to achieve person-centered bathing (Dementia Care Central, 2019; Gozalo et al., 2014; Scales et al., 2018; Whitehead & Golding-Day, 2019; Wolf & Czekanski, 2015). For example, if the patient is confused and becomes agitated as a result of overstimulation when bathing, reduce the stimuli. Turn down the lights and play soft music and/or warm the room before taking the patient into it (Konno et al., 2014). Another alternative is to consider bed bath variations to decrease agitation (Dementia Care Central, 2019). Box 32-1 outlines possible measures to implement to meet the bathing needs of patients with dementia.

Figure 32-1 illustrates several features that add to the safety of a patient taking a shower. Ensure proper cleaning of shower or tub between patient uses to comply with infection control measures, according to facility policy.

Recall **Sonya Delamordo**, the older woman who is going to live at her daughter's home after a stroke. The nurse should incorporate the responsibilities listed here into the teaching plan for Mrs. Delamordo's daughter to ensure the patient's safety with hygiene interventions.

FIGURE 32-1. Examples of features that add to the safety of a patient taking a shower or bath. **A.** Call bell equipped with a pull cord. **B.** Shower equipped with a safety seat and hand rail. (*Source:* Used with permission from Shutterstock. *Photos by B. Proud.*)

BED BATHS

Some patients must remain in bed as a part of their therapeutic regimen but can still bathe themselves. Other patients are not on bed rest but require total or partial assistance with bathing in bed due to physical or mental deficits, such as fatigue or limited range of motion. Implement the following nursing measures to help patients take a bath in bed:

- Provide the patient with articles for bathing. If using a basin of water for bathing, ensure the water is a comfortable

and safe temperature. Place these items conveniently for the patient on a bedside stand or overbed table.

- Provide privacy for the patient. Make sure the call device is within reach.
- Place cosmetics and other skin care products in a convenient place for the patient. Provide a mirror, a good light, and hot water for patients who wish to shave with a razor.
- Assist patients who cannot bathe themselves completely. For example, some patients can wash only the upper parts of the body. Nursing personnel then complete the remainder of the bath.

When bathing a patient, the wipe or washcloth removes some of the outermost skin layer. This sloughed skin may be evident on the wipe or washcloth and in the bathwater and will vary in color depending on the ethnic group of the patient (Andrews et al., 2020). This is important to note, as this does not mean that the patient was dirty—the normal sloughing of the skin is more evident in darkly pigmented people compared with patients with lighter pigmentation (Andrews et al., 2020).

Bathing procedures for patients who require total nursing assistance vary among health facilities. Skill 32-1 on pages 1121 offers one example as a guide. It assumes that the patient can be raised or lowered in bed and that, although the patient may have limited movement, the nurse can manage the patient alone.

DISPOSABLE BATH

The use of disposable bath products is an alternative to the traditional use of soap and water. Disposable bath products are prepackaged in single-use units, heated before use, do not require rinsing, and are equally effective at reducing skin bacteria (Matsumoto et al., 2019; N⊘ddeskou et al., 2015; Veje et al., 2020). There are several variations of this bath. One self-contained bathing system is a package containing 8 to 10 premoistened, disposable washcloths (Fig. 32-2). The unopened package is warmed in the microwave or stored in a warmer until use. Each part of the patient's body is cleansed with a fresh cloth. No rinsing is required. The skin is allowed to air dry (for about 30 seconds) so that the emollient ingredient of the cleaner remains on the skin. Other versions contain disposable wash gloves (Schoonhoven et al., 2015).

Feedback about use of disposable bathing products has been overwhelmingly positive. Nursing staff value the time savings when compared with a traditional bed bath and find it effective and easy to perform (N⊘ddeskou et al., 2015). These products also eliminate the cross-infection risk posed by soap, water, bath basins, and washcloths (Sturgeon et al., 2019). Most patients have commented favorably on the disposable bath and consider it a convenient alternative and preferred in certain circumstances (N⊘ddeskou et al., 2015; Veje et al., 2019). Patients with mild to moderate skin impairments demonstrated an improved skin condition with consistent use of the disposable bath (Matsumoto et al., 2019).

FIGURE 32-2. Commercial self-contained disposable bathing system.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

CHLORHEXIDINE GLUCONATE AND BATHING

The use of chlorhexidine gluconate (CHG) for bathing has been shown to reduce colonization of skin with pathogens and is an important measure utilized by institutions in an attempt to decrease health care–associated infections (HAIs) (Hines et al., 2015). Bathing with chlorhexidine may be used to reduce the incidence of hospital-acquired infections, such as central line–associated bloodstream infections (CLABSIs) and surgical site infections, and to decrease rates of transmission and infection of resistant microorganisms, as well as to reduce the acquisition of or decolonization with multidrug-resistant organisms (Cassir et al., 2015; Martinez et al., 2020; Musuuza et al., 2019; Reynolds et al., 2019; Shah et al., 2016; Urias et al., 2018). Daily bathing with chlorhexidine has also been shown to decrease the incidence of the risk of ventilator-associated pneumonia (Chen et al., 2015).

Some facilities' policies include the use of CHG for all inpatient bathing, except for patients with a history of CHG allergy or intolerance or those younger than age 2 months (Hines et al., 2015). Chlorhexidine can be added to bath water, but is also available, and easier to use, in prepackaged impregnated cloths. CHG-impregnated cloths may result in higher residual skin concentrations after application compared to CHG liquid and water bathing (Rhee et al., 2018). Refer to the accompanying Research in Nursing box.

PROMOTING SKIN HEALTH

An easy and effective way to promote the barrier function of the skin and keep the skin healthy is the daily use of soap substitutes, topical moisturizers and emollients, and barrier products (Andriessen, 2013; Haesler et al., 2018; Lichterfeld et al., 2015; Voegeli, 2019). Soap cleans the skin, but at the same time it removes dirt from the surface, it affects the lipids that are present on the skin and the skin pH. This contributes to drier skin, damaging the barrier function of the skin. The use of mild cleansers with pH close to skin pH is recommended (Lichterfeld et al., 2015; Woods, 2019). The substitution of a nonsoap emollient cleaning agent is an easy way to prevent drying and damage to the skin. The rinseless products mentioned in the description of a disposable bath are examples of nonsoap emollient cleaning agents.

Research in Nursing

BRIDGING THE GAP TO EVIDENCE-BASED PRACTICE

Bathing and Health Care–Associated Infections

Prevention of HAIs is a major challenge for health care providers. Health care facilities constantly strive to implement evidence-based practices to reduce the risk of HAIs for patients and promote patient health. Bathing using chlorhexidine gluconate (CHG) decreases preventable hospital-acquired central line–associated bloodstream infections (CLABSIs) (Reynolds et al., 2019). What interventions can improve implementation and increase consistency in use of bathing with CHG?

Related Research

Reynolds, S. S., Sova, C., McNalty, B., Lambert, S., & Granger, B. (2019). Implementation strategies to improve evidence-based bathing practices in a neuro ICU. *Journal of Nursing Care Quality*, *34*(2), 133–138. https://doi.org/10.1097/NCQ.0000000000000347

The purpose of this observational study was to determine whether using tailored, multifaceted strategies would improve nurses' knowledge/perceptions of CHG bathing, improve compliance with implementation and documentation of daily CHG bathing, and decrease CLABSI rates in a large neuro ICU. Participants included the nurses and nursing assistants employed on the neurology ICU (n = 85) during implementation. Researchers used the Grol and Wensing Model of Implementation to guide the study. Potential barriers and facilitators to implementation of CHG bathing were identified through informal discussion with nursing staff. A knowledge deficit related to the appropriate procedure for bathing was identified as well as a lack of motivation and perceived importance of CHG bathing. Commitment to implementation of evidence-based practices to improve patient care was identified as a strong facilitator to change. Based on this information, staff participated in educational sessions related to the importance and use of CHG bathing, provided by the neuroscience clinical nurse specialist. Printed educational materials related to the use and importance of daily CHG bathing, which included pictures of directions for use of CHG cloths, were disseminated to the unit staff. Two nurse hospital–acquired infection "champions" acted as resources and role models for CHG bathing for the unit staff. Daily CHG bathing was audited for compliance beginning 2 months prior to and weekly for 6 months after implementation of the education; audit information and feedback were provided weekly to staff via email. Nurses' knowledge/perceptions of CHG bathing were measured via a survey prior to and after implementation of the strategies. Protocol compliance was measured using weekly audits of the documentation of use in the electronic health record. Data regarding the hospital's incidence of CLABSIs was provided by the hospital's infection prevention team, reported on a monthly basis, measured by the number of CLABSIs per 1,000 central line days.

Following implementation of the strategies, CLABSI infection rates decreased (p = .031). Statistically significant improvements were seen in bathing documentation (compliance) (p = .013), nurses' knowledge (p =

.001), and perceived importance of CHG bathing (p = .002). The researchers concluded that use of tailored, multifaceted strategies can be used to improve knowledge of and compliance with the use of daily CHG bathing and reduce hospital-acquired infections such as CLABSIs.

Relevance to Nursing Practice

These results can be useful to other facilities in decreasing the risk of hospital-acquired infections such as CLABSIs. Nurses and nursing staff are the primary providers of bathing activities in many health care settings and should consider the implementation of tailored interventions to improve knowledge/perceptions and compliance with daily CHG bathing to improve patient health and decrease health care costs.

Topical emollient agents—also known as moisturizers—can be applied to the skin as a lotion, cream, gel, or ointment. They act to seal water into the skin and replace lipids in the skin, effectively hydrating the skin and recreating its waterproof barrier. Apply topical moisturizers after bathing. Ideally, they should be applied twice a day but may need more frequent application, depending on the skin condition and the product used.

Skin barrier products include creams, ointments, and films. These products are used to protect vulnerable skin and to protect skin at risk for damage caused by excessive exposure to water and irritants, such as urine and feces. They are also used to prevent skin breakdown around stomas and wounds with excessive exudate. Application of one of these products forms a thin layer on the surface of the skin to repel potential irritants. Apply these products by following the manufacturer's recommendations and facility policy. Box 32-2 outlines general skin care principles. Table 32-1 summarizes recommended treatments for dry skin, acne, and skin rashes.

Box 32-2 General Skin Care Principles

- Assess the patient's skin at least daily and after every episode of incontinence.
- Cleanse the skin when indicated, such as when soiled, using a no-rinse, pH-balanced skin cleanser.
- Avoid using soap and hot water; avoid excessive friction and scrubbing.
- Minimize skin exposure to moisture (incontinence, wound leakage); use a skin barrier product as necessary.
- Use skin emollients after bathing and as needed.

Table 32-1 Skin Care Problems

SKIN PROBLEM	DEFINITION	TREATMENT
Dry skin	The skin loses moisture and may crack and peel, or become irritated and inflamed. Symptoms include scaling, flaking, itching, and cracks in the skin.	• Keep baths or showers short, and/or bathe less frequently. • Use warm, not hot water to bathe. • Use as little soap as possible. Try mild cleansers or soaps. • Dry skin thoroughly and gently. • Use moisturizers at least daily. • Drink plenty of water throughout the day. Use a humidifier if the air is dry.
Acne	A skin condition that is characterized by clogged pores (blackheads, whiteheads, pimples), caused by dead skin cells and sebum (oil) sticking together in the pore. Sometimes bacteria that live on the skin also get inside the clogged pore. Inside the pore, the bacteria have a perfect environment for multiplying very quickly. With a large amount of	• Avoid squeezing or picking infected areas because this can spread the infection and cause scarring. • Gently wash the face twice a day and after sweating with a gentle nonabrasive cleanser using your fingertips and lukewarm (not hot) water. • Use oil-free, water-based moisturizers and makeup. Look for products that are "noncomedogenic" or "nonacnegenic." Use cosmetics sparingly to avoid further blockage of the sebaceous ducts. • Keep hair off the face and shampoo regularly. If hair is oily, shampoo daily.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	bacteria inside, the pore becomes inflamed (red and swollen). If the inflammation goes deep into the skin, an acne cyst or nodule appears. Acne can appear on the face, back, chest, neck, shoulders, upper arms, and buttocks.	• Some acne treatments (both over-the-counter and prescription) can increase the skin's sensitivity to sunlight and ultraviolet light. Avoid sun/tanning booth exposure; use sunscreen. • Patients with a lot of acne, cysts, or nodules should consult a dermatologist. • Patients who feel shy or embarrassed as a result of acne; acne leaves scars or darkens skin; or for whom products used do not work should consult a dermatologist.
Skin rashes	Eruptions or inflammations of the skin that may be found anywhere on the body. May be precipitated by skin contact with an allergen, overexposure to the sun, and/or systemic causes, like a reaction to a medication.	• Wash area thoroughly with a mild cleansing agent and rinse well. • Use a moisturizing lotion on a dry rash to prevent itching and promote healing. • Use a drying agent on a wet rash. • Try tepid baths to help relieve inflammation and itching. • Use antiseptic sprays or lotions to help lessen itching, promote healing, and prevent skin breakdown. • Avoid exposure to causative agent, if known. • See a health care provider if symptoms do not respond to treatment or become worse.

PATIENTS WITH BARIATRIC NEEDS

Bariatrics is the science of providing health care for those who have extreme obesity, taking both a patient's weight and the distribution of this weight throughout the body into consideration (Muir & Archer-Heese, 2009). The number of patients who are overweight or obese with bariatric care needs remains a significant problem (Earlam & Woods, 2020; Williamson, 2020). Patients with bariatric care needs are at increased risk for skin integrity issues, including increased risk for alterations in skin integrity and therefore require focused nursing care to prevent skin issues (Earlam & Woods, 2020; Williamson, 2020). Assess the skin of bariatric inpatients twice a day, lifting and separating folds of skin to assess the area, utilizing extra help as necessary (Black & Hotaling, 2015). Nonsoap cleansers should be used and the skin should be dried to prevent retained moisture (Black & Hotaling, 2015; Williamson, 2020). Regular application of barrier creams or sprays can help protect skin from maceration in skin folds, the groin area, perineum and buttock cleft (Williamson, 2020). Currently, there is a lack of evidence related to bathing and hygiene needs or best practice recommendations related to skin hygiene for obese patients (Black & Hotaling, 2015; Cowdell & Radley, 2014; Williamson, 2020). Nurses and patients must work collaboratively to identify the best possible interventions to meet individual personal hygiene needs and preserve skin integrity (Cowdell & Radley, 2014; Dial et al., 2018).

PERINEAL CARE

Perineal cleaning should be performed in a matter-of-fact and dignified manner. Guidelines for Nursing Care 32-1 provides appropriate techniques related to general perineal care. In some cases, a sitz bath may be used to clean and soothe the perineal and anal areas. The procedure associated with administering a sitz bath is discussed in Chapter 33.

Remember **Sonya Delamordo**, who is going to live in her daughter's home after a stroke. The patient may be embarrassed to have her daughter help with perineal care. The nurse would encourage the patient to do as much as she is able, using her left hand. By doing so, the patient maintains some control over the situation, thereby promoting her self-esteem and fostering personal hygiene and independence.

If the patient has an indwelling catheter and the facility recommends daily care for the catheter, this is usually done after perineal care. Care of an indwelling catheter is discussed in Chapter 38.

Incontinent patients require special attention to perineal care. Patients with urinary or fecal incontinence are at risk for incontinence-associated dermatitis (perineal dermatitis), one type of moisture-associated skin damage (MASD)

(Voegeli, 2019). This damage is related to excessive moisture, changes in the pH of the skin, overgrowth of bacteria and infection of the skin, and erosion of perineal skin from friction on moist skin. Early recognition of patients at risk for MASD is critical, along with good skin hygiene (Wounds UK, 2018). Skin care for these patients should include measures to reduce overhydration (excess exposure to moisture), contact with ammonia and bacteria, and friction. Remove soil and irritants from the skin during routine hygiene, and clean the area when the skin becomes exposed to irritants (Voegeli, 2019). Avoid using soap and excessive force for cleaning (Wounds UK, 2018). The use of perineal skin cleansers, moisturizers, and barriers is recommended for skin care for the incontinent patient (Voegeli, 2019). These products help promote healing and prevent further skin damage. Incontinence and nursing care of the patient with incontinence are discussed further in Chapters 33, 38, and 39.

Concept Mastery Alert

For the patient who is incontinent, it is important to keep the perineal area clean and dry. Use nonsoap cleansers and protect the area with moisture barriers.

MASSAGE

Massage has many benefits, including general relaxation and increased circulation. Massage can help alleviate pain (De Luca et al., 2020; Westman & Blaisdell, 2016). Massage of the back, hands, and/or feet may follow the patient's bath or may be provided as part of interventions to promote sleep or increase patient comfort and well-being (De Luca et al., 2020; Momeni et al., 2020; Sharma & Kumari, 2019). Some nurses forego the use of massage due to time constraints; however, in addition to the benefits stated previously, the use of massage provides an opportunity for the nurse to communicate and connect with the patient through touch.

Be aware of the patient's medical diagnosis and health issues when considering the use of massage. For example, a backrub is contraindicated if the patient has had back surgery or has fractured ribs. Refer to Skill 36-1 in Chapter 36 for details regarding giving a back massage.

Providing Vaginal Care

Vaginal mucous secretions are odor free until they combine with air and perspiration. Thus, for vaginal care, using plain soap and water is the most effective means to control odor. Douching is washing or cleaning out the inside of the vagina with water or other fluids (Office of Women's Health, 2019). In normal, healthy women, douching is believed to be unnecessary and is not recommended because it tends to remove normal bacterial flora from the vagina and alter the normal acidic environment. Douching can cause an overgrowth of harmful bacteria and lead to a yeast infection or bacterial vaginosis. If a woman already has a vaginal infection, douching can push the bacteria causing the infection up into the uterus, fallopian tubes and/or ovaries, leading to pelvic inflammatory disease (Office of Women's Health, 2019). Douching has also been linked to problems during pregnancy, STIs, and pelvic inflammatory disease. Douching is not recommended as a routine hygiene measure (Office of Women's Health, 2019).

Guidelines for Nursing Care 32-1

PROVIDING PERINEAL CARE

Perineal care may be carried out while the patient remains in bed. When performing perineal care, follow these guidelines:

- Assemble supplies, and provide for privacy.
- Explain the procedure to the patient, perform hand hygiene, and put on disposable gloves.
- Wash and rinse the groin area (both male and female patients). Use a small amount of a mild nonsoap cleaning agent and water, or disposable cleaning cloths.
- For a female patient, spread the labia and move the washcloth from the pubic area toward the anal area to prevent carrying organisms from the anal area back over the genital area (Figure A). Always proceed from the least contaminated area to the most contaminated area. Use a clean portion of the washcloth for each stroke. Rinse the washed areas well with plain water.
- For a male patient, clean the tip of the penis first, moving the washcloth in a circular motion from the meatus outward (Figure B). Wash the shaft of the penis using downward strokes toward the pubic area (Figure C). Always proceed from the least contaminated area to the most contaminated area. Rinse the washed areas well with plain water. In an *uncircumcised male patient* (teenage or older), retract the foreskin (prepuce) while washing the penis. Pull the uncircumcised male patient's foreskin back into place over the glans penis to prevent constriction of the penis, which may result in edema and tissue injury (MedlinePlus, 2020b). It is not recommended to retract the foreskin for cleaning during infancy and childhood, as injury and scarring could occur (MedlinePlus, 2020b). Wash and rinse the male patient's scrotum. Handle the scrotum, which houses the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

testicles, with care because the area is sensitive.

FIGURE A. Spreading the labia and moving the washcloth from the pubic area toward the anal area.

FIGURE B. Cleaning the tip of the penis, moving the washcloth in a circular motion from the meatus outward.

FIGURE C. Washing the shaft of the penis using downward strokes toward the pubic area.

- Dry the cleaned areas and apply an emollient as indicated. Avoid the use of powder. Powder may become a medium for the growth of bacteria.
- Turn the patient on their side and continue with cleansing the anal area. Continue in the direction of least contaminated to most contaminated area. In the female, cleanse from the vagina toward the anus. In both female and male patients, change the part of the washcloth being used with each stroke until the area is clean. Rinse and dry the area.
- Remove gloves and perform hand hygiene. Continue with additional care as necessary.

Consider **Kylie**, the university student who is concerned about recurring vaginal infections. The nurse at the campus health clinic should include teaching about feminine hygiene self-care behaviors in her care for Kylie.

Deodorants to control odor around the vaginal orifice are unnecessary. No therapeutic benefit from their use has been proven to date. Use of these special deodorants is not a substitute for keeping the area clean; female patients often require teaching on this subject. If patients insist on using them, explain they are intended for external use only. They should not be placed on sanitary napkins or tampons, should not be used on broken skin areas. Use is not recommended because of reported irritation and rashes, and urethral irritation (Mayo Foundation for Medical Education and Research, 2020a; Sparks, 2018).

Providing Care for Body Piercing

Body piercing has increased in popularity and acceptance in recent years, regardless of socioeconomic and cultural background. Piercings can be found on the face (tongue, lips, nose, eyebrows), ears, neck, arms, legs, torso, navel, and genitals of patients. Nurses and other health care providers need to provide safe and effective care for patients with body piercings, including accurate assessment and site care. Basic wound care used for body piercings is usually called "aftercare." Aftercare techniques are used for the new piercing and whenever the piercing fistula has become disrupted through injury or exhibits signs of infection or inflammation (Association of Professional Piercers, 2020; Mayo Foundation for Medical Education and Research, 2020b). Guidelines for Nursing Care 32-2 provides appropriate techniques related to piercing site care.

Tongue piercings may increase the risk of periodontal destruction in teeth with close proximity to the piercing, and should be taken into consideration during an oral assessment (Schmidt et al., 2019). Piercing jewelry may cause difficulty with placement of treatment devices, and can interfere with diagnostic imaging, such as magnetic resonance imaging (MRI) or computerized axial tomography (CT scan), or contribute to patient injury during MRI or other procedures, such as surgery or Foley catheter placement (Davis, 2014; DeBoer et al., 2011; Durkin, 2012; Rademeyer et al., 2020). Some health care providers routinely recommend that all jewelry is removed, whereas others state that it should not be removed unless necessary (D'Alesandro, 2014; Davis, 2014; Rademeyer et al., 2020). Various devices, such as plastic jewelry, are available to be used to keep the piercing tract open when removal is required (Van Hoover et al., 2017). The use of an intravenous catheter to maintain piercing patency has also been suggested (Rademeyer et al., 2020). Nurses should consult facility policies related to removal of body piercing jewelry.

Assisting With Oral Hygiene

The mouth requires care, particularly during illness, but sometimes care must be modified to meet a patient's needs. Adequate oral hygiene care is imperative to promote the patient's sense of well-being and comfort, and prevent deterioration of the oral cavity (Kisely, 2016; Riley, 2018). Poor oral hygiene contributes to the colonization of the oropharyngeal secretions by respiratory pathogens. Diligent oral hygiene care can improve oral health and limit the growth of pathogens in the oropharyngeal secretions, decreasing the incidence of aspiration pneumonia, community-acquired pneumonia, nonventilator health care–associated pneumonia (NV-HAP), and ventilator-associated pneumonia (VAP) (AACN, 2017; Chick & Wynne, 2020; Jenson et al., 2018; Quinn et al., 2020). Comprehensive oral care that includes thorough mechanical cleaning is an important part of care to achieve oral health outcomes for patients in all settings (Barbe et al., 2020; Chick & Wynne, 2020; Chicote, 2019; Gibney et al., 2019; Kisey, 2016).

An oral assessment tool can assist with assessment of the status of the oral cavity, as well as help to determine the frequency and procedure for oral care (Chick & Wynne, 2020; Chicote, 2019; McCormick et al., 2019). If the patient can assist with mouth care, provide the necessary materials and help the patient as necessary (Skill 32-2 on pages 1126–1131).

Physical limitations, such as those associated with aging, often lead to less-than-adequate oral hygiene (Thomas, 2019). The dexterity required for adequate brushing and flossing may decrease with age or illness. Older adults may be dependent on caregivers for oral hygiene. Patients with cognitive impairment, such as dementia, and mental illness are also at risk for inadequate oral hygiene (Brennan & Strauss, 2014; Jablonski et al., 2018; Kadia et al., 2014; Lee et al., 2013; Red & O'Neal, 2020). If the patient is unable to perform oral hygiene, make certain that the mouth receives care as often as necessary to keep it clean and moist, as often as every 1 or 2 hours if necessary. This is especially important for patients who cannot drink or are not permitted fluids by mouth. Refer to Box 32-3 for suggestions to meet the oral hygiene needs for patients with cognitive impairments. Skill 32-3 on pages 1131 identifies techniques for administering oral hygiene to dependent patients. Moisten the mouth with water, if allowed,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and lubricate the lips frequently to keep the membranes well moistened.

Guidelines for Nursing Care 32-2

Providing Body Piercing Care

- Perform hand hygiene before providing care. Explain what you are going to do. Put on gloves.
- Clean the jewelry and the piercing site of all crust and debris. Clean the site with mild soap and warm water or normal saline solution. Use a cotton swab to gently remove any crusting. Rinse well. Remove gloves. Perform hand hygiene.
- Advise patients to avoid the use of alcohol, hydrogen peroxide, and ointments at the site.
- Advise patients to avoid immersion in unclean water such as baths, pools, hot tubs, or lakes during healing.
- Oral piercing aftercare includes rinsing with an antibacterial, alcohol-free mouthwash for 30 to 60 seconds after meals and at bedtime. The patient should brush the teeth with a new, soft-bristled toothbrush.
- Advise patients to avoid oral tobacco use.
- Most piercings take 6 to 8 weeks to heal, but some may take several months or a year to heal.

Source: Adapted from American Academy of Family Physicians. (2019, July 19). *Body piercing*. https://familydoctor.org/body-piercing/?adfree=true; McBride, D. L. (2018). Clinical guidance to tattooing and piercing among youth. *Journal of Pediatric Nursing*, *39*, 83–84. https://doi.org/10.1016/j.pedn.2017.11.012; and Rademeyer, C., Farley, C. L., & Van Hoover, C. (2020). Health implications and counseling considerations for individuals with piercings and tattoos. *Nursing for Women's Health*, *24*(3), 210–227. https://doi.org/10.1016/j.nwh.2020.03.006

The use of chlorhexidine gluconate (CHG) as part of oral hygiene has been integrated into oral hygiene regiments and is available as an oral rinse, oral spray, and dental gel (AACN, 2017; de Camargo et al., 2019). The use of CHG as part of protocols for systematic oral care for critically ill patients has been shown to reduce risk of ventilator-associated pneumonia (VAP) (AACN, 2017; Chen et al., 2015).

Box 32-3 **Meeting the Oral Hygiene Needs of Patients With Cognitive Impairments**

- Choose a time of day when the patient is most calm and accepting of care.
- Enlist the aid of a family member or significant other.
- Break the task into small steps and provide short, simple instructions.
- Provide distraction, such as playing favorite music, while providing care.
- Allow the patient to participate. The nurse can put a hand over the patient's hand to guide the activity.
- Start the activity, showing the patient what to do, then let the patient take over.
- Withdraw and try again later if the patient strongly refuses care.
- Document effective and ineffective interventions to provide appropriate information for staff to give consistent, thoughtful, person-centered care.

Patient education about oral hygiene is an important aspect of promoting good oral hygiene. Consider providing information about oral hygiene techniques and the importance of regular (twice yearly) dental visits to treat and prevent oral health problems. Emphasize that regular checkups aid in catching problems early and make any problems more manageable (Cleveland Clinic, 2019; MFMER, 2018). Refer to the PICOT in Practice box (on page 1108) for additional discussion related to oral hygiene and children.

TOOTHBRUSHING AND FLOSSING

Brush and floss teeth twice a day and rinse the mouth after meals. A soft-bristled toothbrush should be small enough to reach all teeth. Clean and dry all brushes between uses. Bacteria do most damage directly after eating, so make sure the patient brushes the teeth immediately after eating or drinking. In addition, clean the tongue with the toothbrush or a tongue scraper (MFMER, 2019a). Use a toothbrush even when the patient has no or few teeth. It is the only effective way to remove plaque (a thin film of bacteria that forms on teeth) and debris.

Automatic toothbrushes, electric or battery operated, are simple to use and can be used to removing debris and

plaque and clean the teeth effectively. Use of an electric toothbrush provides superior oral hygiene care when oral hygiene is provided by a caregiver (Vannah & Sammarco, 2019). These devices are very useful for patients with arthritis or other conditions that make it difficult to brush effectively (MFMER, 2019a).

The toothbrush cannot reach areas between the teeth where food lodges and plaque can build up, so flossing at least once a day is recommended (American Dental Association [ADA], n.d.b). Flossing removes the debris that the toothbrush cannot and helps to break up colonies of bacteria. Other interdental cleaners may be used as well, such as cone-shaped brushes, and are particularly useful for patients who have a hard time handling dental floss or are unable to perform their own oral care (ADA, n.d.b). Pressurized water spray units (water flossing) are available to assist with oral hygiene to remove plaque and reduce gingivitis (ADA, n.d.d). Water flossing devices can be a useful option for patients who have trouble flossing by hand (ADA, n.d.d). However, if too much water pressure is used, particles of debris may be forced into tissue pockets, leading to gum damage. Therefore, patients should discuss use of these devices with a dentist.

Toothpastes and powders (dentifrices) aid the brushing process and usually have a pleasant taste that encourages brushing, especially by children. Most dentifrices are safe to use, but those containing harsh abrasives may scratch the enamel of the teeth and thus are not recommended. Salt and sodium bicarbonate are far less expensive than proprietary products on the market and just as effective for short-term use. However, these products lack fluoride and should not be used exclusively. Dentifrices containing stannous fluoride and antitartar agents, as well as antiplaque rinses, decrease dental caries and are recommended for use (ADA, 2019; ADA, n.d.e).

Unfolding Patient Stories: Christopher Parrish • Part 2

Recall from Chapter 23, **Christopher Parrish**, age 18, who has cystic fibrosis and frequent respiratory infections. He recently started college and is living in the dormitory. What questions can the nurse ask to identify his current hygiene practices and preferences? How would the nurse assess the adequacy of Christopher's personal hygiene behaviors? What education can the nurse provide to promote good hygiene and reduce his risk for infection?

Care for Christopher and other patients in a realistic virtual environment: *vSim for Nursing* (thepoint.lww.com/vSimFunds). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

PICOT in Practice

ORAL HEALTH AND SCHOOL DENTAL PROGRAM

Scenario: You are a school nurse discussing the importance of oral health with a group of parents and children at an after-school event. One area you have stressed is the importance of oral hygiene to reduce infection, plaque accumulation, and the risk of gum disease. Oral hygiene includes brushing to clean the surfaces of the teeth, flossing to clean the surfaces between the teeth, and regular dental checkups. Some parents share concerns that their children have developed cavities at their last dental visit. You notice there are inconsistencies in the regular intervals between dental checkups reported by the parents.

You consider if a school dental screening program for oral health would benefit parents and children living in the community.

- **Population:** Children at risk for gum disease
- **Intervention:** School dental screening programs
- **Comparison:** Regular interval dental checkups
- **Outcome:** Improved oral health status
- **Time:** 12 months

PICOT Question: Do school dental screening programs compared to regular interval dental checkups improve oral health status in children living in the community over 12 months?

Findings:

1. Arora, A., Khattri, S., Ismail, N. M., Kumbargere Nagraj, S., Eachempati, P. (2019). School dental screening programmes for oral health. *Cochrane Database of Systematic Reviews*. Issue 8. *Art. No.:* CD012595.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

https://doi.org/10.1002/14651858.CD012595.pub3

This included seven trials with 20,192 children ages 4 to 15 years and follow-up for 3 to 8 months. A very low certainty of evidence was found, which was insufficient to draw conclusions about whether there is a role for traditional school dental screening in improving dental care. Furthermore, when compared to traditional screening, there was no evidence of a difference in regular dental care (very low–certainty evidence).

2. Fee, P. A., Riley, P., Worthington, H. V., Clarkson, J. E., Boyers, D., Beirne, P. V. (2020). Recall intervals for oral health in primary care patients. *Cochrane Database of Systematic Reviews*. Issue 10. *Art. No.:* CD004346. https://doi.org/10.1002/14651858.CD004346.pub5

This included two studies with data from 1,736 participants. One study was conducted in a public dental service clinic in Norway and involved participants younger than age 20 years who were regular attenders at dental appointments. The other study was conducted in U.K. general dental practices and involved adults who attended regularly. It compared the effects of 6-month, 24-month, and risk-based recall intervals and measured outcomes at 4 years. For adults attending dental checkups in primary care settings, there is little to no difference between risk-based and 6-month checkups in the number of tooth surfaces with any caries, gingival bleeding, and oral health–related quality of life over a 4-year period (high-certainty evidence). The available evidence on recall intervals between dental checkups for children and adolescents was uncertain.

Strength of Evidence: Level I: systematic review

Recommendation: There is insufficient evidence to draw conclusions about whether there is a role for traditional school dental screening in improving dental care in children. Adults who see their dentist for a checkup every 6 months or at personalized intervals based on their dentist's assessment of their risk of dental disease does not affect tooth decay, gum disease, or quality of life. If parental dental care and preventative practices are any indication of childhood practices, children who see their dentist for a checkup every 6 months or at personalized intervals does not affect tooth decay, gum disease, or quality of life. High-quality studies that measure the impact of screening on oral health and are carried out over longer periods of time are needed.

MOUTHWASHES

Therapeutic mouth rinses that reduce bacteria can help reduce plaque, gingivitis, tartar (hardened plaque) and also freshen breath. Anticavity rinses with fluoride help protect tooth enamel to help prevent or control tooth decay (ADA, 2019). Swabs and mouthwash with alcohol should be avoided (Woon, 2020).

Halitosis is often a sign of something more serious than a strong smell that lingers after some foods (ADA, n.d.f). Halitosis may be the result of dental issues (cavities, gum disease); mouth, nose, and throat infections; dry mouth; or other chronic conditions (ADA, n.d.f). If the cause of halitosis is poor oral hygiene, a daily dental cleaning routine should reduce the odor.

Sometimes, halitosis may be systemic in nature. For example, the odor of onions and garlic on the breath comes from the lungs, where the oils are being removed from the bloodstream and eliminated with respiration. A mouthwash cannot remove halitosis when odors are being eliminated by respiration. If bad breath persists, a patient should consult with a dentist (ADA, n.d.f).

DENTURE CARE

Failing to wear dentures for a long period allows the gum line to change, thus affecting the fit of the dentures. It is not recommended, however, that dentures be worn continuously (24 hr/day) in order to reduce or minimize irritation of the oral tissues (American College of Prosthodontists, n.d.).

Patients with dentures are more likely to keep them in the mouth if they are kept clean. If the patient cannot care for them, the nurse must ensure that the dentures are clean. Use care when handling a patient's dentures because they represent a considerable financial investment, and replacement for damage or loss is expensive. Remove and rinse dentures and mouth after meals.

Dentures should be cleaned daily to reduce plaque and potentially harmful microorganisms (ADA, n.d.c). Daily cleaning includes brushing with a nonabrasive denture cleanser or mild dishwashing liquid with a denture brush (American College of Prosthodontists, n.d.).

FIGURE 32-3. Cleaning dentures.

When cleaning dentures for a patient, put on gloves and hold them over a basin of water or a sink lined with a washcloth or soft towel (Fig. 32-3) so that if they slip from your grasp, they will not fall onto a hard surface and break. If necessary, grasp the dentures with a 4″ × 4″ piece of gauze to help prevent them from slipping out of your gloved hands. Use cool or lukewarm water to cleanse them. Hot water may warp the plastic material of which most dentures are made. Use a denture brush and denture cleanser. Do not use toothpaste as it can be too harsh for denture surfaces (American College of Prosthodontists, n.d.). Rinse dentures thoroughly after soaking and brushing, prior to reinsertion into the mouth. Give the patient the opportunity to brush the gums and tongue and rinse the mouth before the dentures are replaced to stimulate circulation and help remove plaque (ADA, n.d.c). Assist the patient with care as necessary.

Store dentures in water when not in the patient's mouth (American College of Prosthodontists, n.d.). Leaving dentures to dry can cause warping. If the patient has been instructed to remove dentures while sleeping, a disposable denture cup is convenient and easy to use. A denture-cleaning tablet can be added to the water overnight (Woon, 2020). Advise the patient not to wrap dentures in toilet tissue or disposable wipes because these are likely to be thrown away.

Providing Eye Care

Normally, the eyes are kept clean with lacrimal secretions. During illness, the eyes may produce more secretions than normal and may appear glass-like. Use the following techniques when secretions adhere to the eyelashes and become dry and crusty or when discharge is present:

- Wear gloves during the cleaning procedure.
- Use water or normal saline and a clean washcloth or compress to clean the eyes. Never use soap to clean the eyes because soap is irritating to eye tissues.
- Dampen a cleaning cloth with the solution of choice and wipe once while moving from the inner canthus to the outer canthus of the eye. This technique minimizes the risk for forcing debris into the area drained by the nasolacrimal duct. Turn the cleaning cloth and use a different section for each stroke.
- Continue this technique, using a different section of the cleaning cloth for each stroke, until the eye is clean.
- If the eyelashes are matted with secretions or debris that cannot be removed by wiping, apply a warm, wet compress to the closed eye for 3 to 5 minutes to loosen the secretions so that they may be removed in a painless manner.

CARE OF THE UNCONSCIOUS PATIENT'S EYES

Patients with diminished or absent blink (corneal) reflexes and patients whose eyelids remain open require frequent eye care, at least every 4 hours. If the eye is not kept moist, corneal ulceration may result from excessive drying of the eye (Morton & Fontaine, 2018). Nursing measures include using saline or artificial tears or lubricant eye ointment based on the prescribed interventions or facility protocol, to lubricate the eye and a protective eye covering to keep the eye closed (Morton & Fontaine, 2018).

EYEGLASS CARE

Eyeglasses are essential for many people and represent a considerable financial investment. Take special precautions to prevent them from being broken or lost. Encourage patients who need glasses to wear them to avoid eyestrain.

Many eyeglasses have plastic lenses, which are considerably lighter in weight than glass lenses but correct vision just as well. Plastic lenses scratch easily. Whenever setting down glasses, make sure they are placed with the lenses up.

Clean eyeglasses over a towel, so that if they slip they will not become scratched or broken. Use warm water and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

soap or a special cleansing preparation. Hot water may warp plastic lenses and frames. Rinse the glasses well after cleaning them with soap and water; dry them with a clean, soft non-lint cloth (Cleveland Clinic, 2015). Paper products that are made of wood pulp increase the risk of scratching the lenses, so do not use a dry paper tissue to clean eyeglasses. Do not use silicone tissues to clean plastic lenses.

CONTACT LENS CARE

A contact lens is a small disc worn directly on the eyeball. It stays in place by surface tension of the eye's tears. Contact lenses are either rigid (hard) or soft. Rigid gas permeable (RGP) lenses are more inflexible than soft lenses. Soft lenses are made of a plastic material that absorbs water to become soft and pliable. They are brittle when dehydrated and absorb water when placed in a solution, usually normal saline, or when in contact with tears. Soft lenses may be used for daily wear or extended wear. Disposable soft lenses are also available.

People who wear contact lenses need to take special precautions to keep the lenses free of microorganisms that may lead to eye infections and to avoid injuring or scratching the surface of the eye. Patients should always perform hand hygiene before touching eye surfaces and lenses. Caution lens wearers about eye irritation in the presence of noxious vapors or smoke. Remind lens wearers that lenses should not come into contact with cosmetics, soaps, or hair sprays because eye irritation may result. Patients should use only commercially prepared, sterile contact lens solutions and discard the solution in the contact lens case each time the lenses are disinfected and stored (MFMER, 2019b). Patients should never rinse with tap water or saliva (Cleveland Clinic, 2020; MFMER, 2019b). Urge the patient to immediately report any adverse reaction related to contact lens use.

The cornea, which consists of dense connective tissue, does not have its own blood supply. It is nourished primarily by oxygen from the atmosphere and from tears. In a patient who wears contact lenses, the cornea requires more than its normal supply of oxygen because its metabolic rate increases. To allow the cornea to receive a maximal supply of oxygen, contact lenses should be worn and removed according to the type and manufacturer's recommendations. Excessive tearing, pain, and redness signal the need to remove lenses. Lenses should be cleaned and stored as prescribed. Different types of lenses require special care and certain types of cleaning/storage products. Sleeping without removing any contact lens is not recommended as the incidence of serious eye infections is greatly increased (Cleveland Clinic, 2020).

If a patient wears contact lenses but cannot remove them, the nurse may be responsible for removing them. This may occur, for example, when the nurse is caring for an unconscious patient. Whenever an unconscious patient is admitted without any family present, always assess to determine whether the patient wears contact lenses. If an eye injury is present, do not try to remove lenses because of the danger of causing an additional injury.

Providing Ear Care

Other than cleaning the outer ears, little intervention is needed for routine hygiene of the ear. After the ears are washed, dry them carefully with a soft towel so that water and cerumen (wax) are removed by capillary action. Forcing the towel into the ear for drying or using a cotton-tipped applicator may aid in the formation of wax plugs. Using bobby pins, hairpins, paper clips, or fingernails to remove wax from the ear is extremely dangerous because these may injure or puncture the eardrum.

If the patient uses a hearing aid, check the batteries routinely and clean the earpieces or ear mold daily with mild soap and water or according to the manufacturer's instructions. A whistling sound that is audible when the hearing aid is held in the hand with the power on and the volume high indicates that the battery is functioning properly. Figure 32-4 illustrates three types of hearing aids. Refer to Chapter 8 for strategies nurses can use to promote communication with a hearing-impaired patient. If hearing loss is mild and the patient is not using a hearing aid, the following suggestions may help to improve hearing and should be included in any patient teaching:

- Avoid noisy places for conversation.
- Choose well-lit places where it is easier to look at the speaker's face, lips, and hands for cues to the conversation.
- Cup your hand behind your ear.
- Ask people to face you when they are speaking to you.
- Ask people to repeat what they said, if it was not clear to you, and to speak slowly.
- Consider buying amplifying devices so that you can hear your television and radio without turning up the sound.

Providing Nose Care

The best way to clean the nose is to blow it gently. Both nostrils should be open while doing this. Closing one nostril adds to the danger of forcing debris into the eustachian tubes. Irrigations are usually contraindicated because of the danger of forcing material into the sinuses.

If the external nares are crusted, applying a warm, moist compress helps to soften and remove the crusts. Disposable paper tissues are recommended for nasal secretions. A cotton-tipped applicator may be used to clean the opening of the nares, but with great care to avoid injury. Never introduce the applicator into the nares.

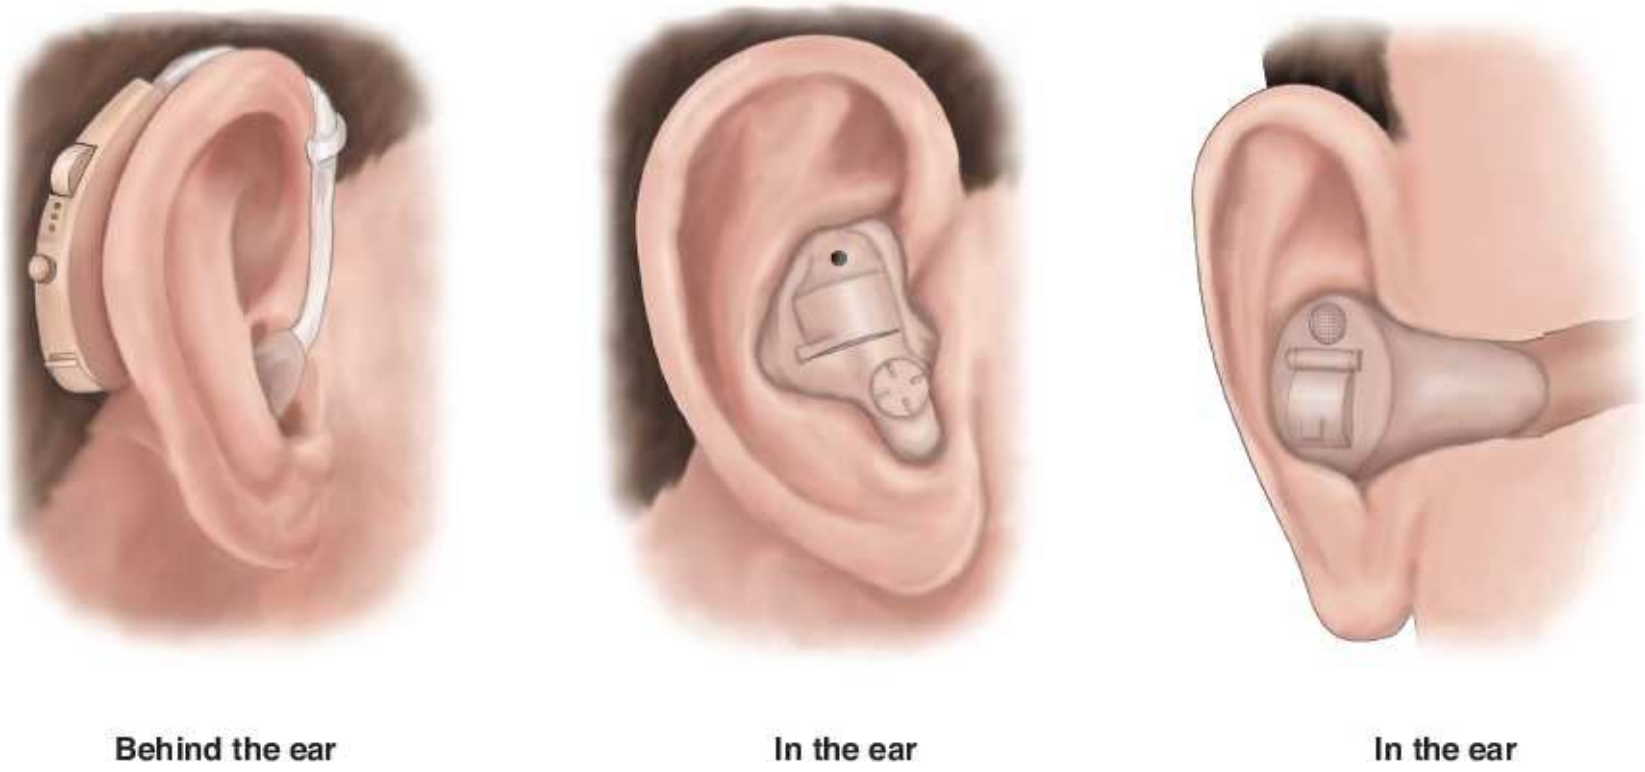

FIGURE 32-4. Several types of hearing aids.

Providing Hair Care

Demonstrate cultural consideration by grooming the patient's hair in the manner and the style preferred by the patient. Hair that becomes entangled is difficult to comb. Combing tiny sections of hair at a time may be necessary if a patient's hair has not been combed for even 1 day. One way to protect long hair from matting and tangling is to ask the patient for permission to braid it. Parting the hair in the middle on the back of the head and making two braids, one on either side, prevents the discomfort of lying on one heavy braid on the back of the head. When braiding a patient's hair, ensure that the hair is not pulled too tightly.

Tightly curled (kinky) hair is normally dry and curly and becomes matted and tangled easily. Use a comb with wide-spaced teeth and work the hair through from the neckline upward toward the forehead. Some people have their hair straightened, but even after this process, it may be difficult to untangle the hair when the person is confined to bed. Some patients with this type of hair style their hair in small braids. The braids are not undone for shampooing and may need to have a lubricant or oil applied daily to prevent hair strands from breaking.

Occasionally, a patient's hair is almost hopelessly matted, and cutting the hair may be necessary. Usually the patient signs a written consent before a patient's hair is cut. Also, as appropriate, discuss with a member of the patient's immediate family the necessity of cutting the hair.

SHAMPOOING THE HAIR

The hair, which is exposed to the same dirt and oil as the skin, requires washing as often as necessary to keep it clean. Wash the comb and brush each time the hair is washed and as frequently as necessary between shampoos. Some health care facilities may have beauticians and barbers to assist with hair care, including shampooing, but this does not relieve the nurse of the responsibility.

Before shampooing the hair, brush or have the patient brush and comb the hair well to stimulate the scalp and undo tangled hair. The patient may then shampoo the hair while showering, if able. In some settings, shampooing a patient's hair is a prescribed intervention.

Shampoo caps are available and are being used with increasing frequency (Fig. 32-5). These commercially prepared, disposable caps contain a rinseless shampoo product. Warm the cap in the microwave or store it in a warmer until use. Place the cap on the patient's head and massage the hair and scalp through the cap, to lather the shampoo. After shampooing for the manufacturer's suggested length of time, remove and discard the cap.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 32-5. Using a shampoo cap to clean a patient's hair.

If regular shampooing is inappropriate or is contraindicated by the patient's condition, other products for use at the bedside are available. These products do not require rinsing and are available as foams, concentrates, and dry powders. Apply the foam or concentrate cleaner and lather the product or distribute through hair according to the instructions on the label.

After shampooing or application of a foam or concentrate hair-cleaning product, towel-dry the patient's hair. Comb and style the hair according to the patient's preference. It may be appropriate to keep the head covered with a towel until the hair dries, to help minimize chilling of the patient. Guidelines for Nursing Care 32-3 on page 1112 provides one technique to shampoo hair for patients on bed rest at home or in a facility.

SHAVING

Grooming of body hair other than hair on the head can be an important part of a patient's self-esteem and well-being. Patients with beards or mustaches may require nursing assistance to keep the beard and mustache clean. Never trim or shave a patient's beard or mustache without the patient's consent. Female patients may require assistance with shaving underarm and leg hair, depending on the patient's personal preference and abilities. Standard razors with a blade tend to give a closer shave than do electric razors, but many patients find electric razors more convenient and practical. Electric shavers are usually recommended when the patient is receiving anticoagulant therapy or has a bleeding disorder (Hartford HealthCare, 2019) and are especially convenient for ill and bedridden patients. Shaving after a warm bath or shower softens the hair, making the process easier (Hartford HealthCare, 2019). The technique for shaving patients with a standard razor who cannot shave themselves is described in Guidelines for Nursing Care 32-4 (on page 1112).

TREATING PEDICULOSIS

Several commercial preparations, called pediculicides, are available for the treatment of pediculosis. These drugs destroy the lice and their eggs or nits. Two treatments may be necessary before all the nits are destroyed. The procedures and the medications used for the treatment of pediculosis vary among health facilities. The partners of patients with pubic infestation from within the previous month should be informed that they are at risk for infestation and should be treated (CDC, 2019a).

When educating the patient, stress the importance of carefully following the instructions and finishing the treatment, as indicated. Failure to comply with product instructions and/or finishing the treatment has produced lice that are resistant to pediculicides on the market. Drugs used to treat lice can be dangerous if they are misused or overused (CDC, 2019a). Additional interventions and patient education topics related to head lice are highlighted in Teaching Tips 32-1 on page 1113.

Guidelines for Nursing Care 32-3

Shampooing a Patient's Hair in Bed

Follow these guidelines for shampooing the hair of patients on bedrest.

- Perform hand hygiene.

- Identify the patient. Explain procedure to the patient.
- Prepare several pitchers with comfortably warm (no more than 120°F) water for washing and rinsing, shampoo, one or two towels for drying, and a receptacle to receive wash and rinse water.
- Place a protective pad and a plastic hair-washing tray if one is available (see Figure) under the head. (Alternatively, a large trash bag can also be used under the patient's head and extended over the side of the bed to catch the water.)
- Place the patient in a position over the pad so that water drainage is directed into the receptacle.
- Wet the hair, apply shampoo, and massage the scalp well while washing the hair.
- Rinse the hair and reapply shampoo for a second washing, if indicated.
- Rinse the hair thoroughly.
- Apply conditioner if requested or if the scalp appears dry.
- Towel-dry the patient's hair. Apply additional hair product, such as leave-in conditioner, oil or pomade, based on patient preferences. Comb and style the hair according to the patient's preference.
- Keep the head covered with a towel until the hair dries, to help minimize chilling the patient.

Providing Fingernail Care

The following are recommended techniques for the care of fingernails:

- Trim the nails straight across, then round the tips in a gentle curve. Do not trim so far down on the sides that the skin and cuticle are injured.
- Remove hangnails, which are broken pieces of cuticle, by carefully clipping them off. Do not pull or rip off hangnails (MFMER, 2019c).
- Gently push cuticles back off the nail when soft and pliable after washing in warm water, using a blunt instrument or a terry cloth.

▶ Guidelines for Nursing Care 32-4

Shaving with a Standard Razor

- Perform hand hygiene.

- Identify the patient. Explain procedure to the patient.
- Cover patient's chest with a towel or waterproof pad. Fill bath basin with comfortably warm (no more than 120°F) water.
- Press a warm washcloth on the patient's skin to soften the hair.
- Dispense shaving gel/cream into palm of hand. Rub hands together, then apply to area to be shaved in a layer approximately 0.5 inch thick.
- With one hand, hold the skin steady at the area to be shaved. Using a smooth stroke, begin shaving. *If shaving the face,* shave with the direction of hair growth in downward, short strokes (see Figure). *If shaving a leg,* shave against the hair in upward, short strokes.
- Remove residual shaving cream with a wet washcloth.
- If patient requests, apply aftershave or lotion to area shaved.
- Remove and discard gloves and perform hand hygiene.

Shaving the face.

Teaching Tips 32-1

DEALING WITH HEAD LICE

Health Topic	Teaching Tip	Why Is This Important?
Who is at risk for getting head lice?	Preschool- and elementary-aged children and families/household members/caregivers are most often affected. Infection can occur after contact with someone who has lice.	Lice can infect any person, regardless of hygiene practices or social status.
How do you become infected with head lice?	Spread by direct contact with the hair of an infested person. Head-to-head contact provides greatest risk of transmission. Uncommonly spread by sharing clothing (hats, scarves, coats, sports uniforms) or belongings (hair ribbons, barrettes, combs, brushes, towels, stuffed animals). Uncommonly spread by lying on a bed, couch, pillow, or carpet that has recently been in contact with an infested person.	Avoid head-to-head (hair-to-hair) contact during play and other activities. Do not share clothing such as hats, scarves, coats, sports uniforms, hair ribbons, or barrettes. Do not share combs, brushes, or towels. Do not lie on beds, couches, pillows, carpets, or stuffed animals that have recently been in contact with an infested person.
What are the signs and symptoms of head lice infestation?	Tickling feeling on scalp; itching; sores on the head caused by scratching. Irritability and difficulty sleeping (head lice are most active in the dark). Lice may be seen especially behind the ears and near the neckline at the back of the neck.	The faster the lice are noticed, the easier they are to eradicate.
How is head lice infestation treated?	Apply a pediculicide[a] according to the manufacturer's directions. Hats, scarves, pillowcases, bedding, clothing, and towels worn or used by the infested person in the 2-day period just before treatment is started can be machine washed and dried using the hot water and hot air cycles (lice and eggs are killed by 5 minutes of exposure to temperatures greater than 128.3°F) Items that cannot be laundered may be dry-cleaned or sealed in a plastic bag for 2 weeks. Soak combs and brushes in hot water (at least 130°F) for 5 to 10 minutes. Vacuum the floor and furniture, particularly where the infested person sat or lay.	All head lice must be killed or removed or a reinfestation may occur. Retreatment of head lice usually is recommended because no approved pediculicide completely kills all lice eggs.

[a]Women who are pregnant or breastfeeding should not use pediculicides without consulting with their health care provider. Consult a health care provider before using pediculicides on a person who has allergies, asthma, or other medical conditions.

Source: Information obtained from Centers for Disease Control and Prevention (CDC). (2019, September 11). *Parasites—Lice*. https://www.cdc.gov/parasites/lice/

- Apply an emollient or moisturizer to the nails and cuticles to help prevent hangnails.
- Clean under the nails with a blunt instrument, being careful not to injure the area where the nail is attached to the underlying tissue.

Splitting and peeling of the nails can be caused by repeated or prolonged contact with water. Teach the patient to avoid contact with soap and water as much as possible, and to wear cotton-lined rubber gloves when washing dishes, cleaning, or using harsh chemicals. Encourage the frequent use of a good hand cream, and avoid using polish remover with acetone, which tends to dry the nails (MFMER, 2019c).

Providing Foot Care

Proper foot care is important at any age. It becomes even more so with aging and when conditions such as circulatory disturbances or diabetes mellitus are present. Keep toenails at a moderate length and cut toenails straight across the toes (MFMER, 2019d). Encourage patients with diabetes and peripheral vascular disease to schedule annual foot checks with their healthcare provider or podiatrist and to see an advanced practice provider or podiatrist for treatment related to bunions, corns, or calluses (American College of Foot and Ankle Surgeons, n.d.; Beuscher, 2019; MFMER, 2017). Guidelines for Nursing Care 32-5 on page 1114 highlights appropriate techniques related to foot care.

Providing Environmental Care

A patient's environment can improve or detract from the person's sense of well-being. A patient's environment can consist of a room in a facility, such as a hospital, one or more rooms in the patient's home or apartment, or something in-between. Regardless of the setting, ensure that the area is clean and clutter-free, safe, and pleasant. Patients may be in an individual "single" room or a multiple-bed room. Single rooms provide for patient privacy and dignity, and ensure confidentiality (Roos et al., 2020). Single rooms are also often part of infection control measures. However, patients in single rooms may feel isolated and experience loneliness (Roos et al., 2020). Multiple-bed rooms offer the opportunity for socialization, communication, and support, but may be associated with a loss of privacy, increased noise, and less control over the environment (Hasan Tehrani et al., 2018; Roos et al., 2020). Nurses must take these factors into consideration and implement actions to support patient-centered care in all room environments.

Guidelines for Nursing Care 32-5

Providing Foot Care

- Bathe the feet daily in a mild soap and lukewarm water solution. Avoid soaking the feet. Be sure to clean the interdigital area.
- Rinse the feet to remove soap residue that can dry and irritate the skin.
- Dry feet thoroughly, including the area between the toes.
- Apply a moisturizer to feet if they are dry. Patients with diabetes and peripheral artery disease should apply moisturizer on the tops and bottoms of the feet to keep the skin soft, but not between the toes. These patients should sprinkle talcum powder or cornstarch between the toes to keep the skin dry (MFMER, 2017).
- Consider using an antifungal foot powder if necessary to prevent fungal infections, such as athlete's foot.
- Patients with diabetes should file the nails; avoid using scissors or nail clippers, which may slip and injure tissues. Nondiabetic patients should avoid digging into or cutting the toenails at the lateral corners when trimming the nails.
- Do not cut off corns or calluses. Avoid commercial removers because they may contain ingredients that can lead to development of infection and ulcers. Consult a podiatrist, a health care provider who treats foot disorders, when corns or calluses are present.
- Explain the dangers of going barefoot. Skin on the feet may be injured, or athlete's foot may be acquired in public showers.
- Advise patients to wear appropriate footwear. Break in new shoes gradually. Improperly fitting shoes can lead to corns, calluses, bunions, and blisters. The soles should be flexible and nonslippery and the heel heights should be safe and offer appropriate support. Shoes with rough ridges, wrinkles, or tears in the linings should be discarded or repaired.
- Advise patients to wear cotton socks, which provide warmth and absorb perspiration.
- Teach patients to avoid wearing knee-high stockings, and to not sit with the knees crossed because this can obstruct the circulation to the lower extremities and feet.
- Prop the feet up above the level of the hips a few minutes several times a day if the feet swell.
- Avoid using heating pads and hot-water bottles because of the danger of blistering and burning the feet.
- Report any signs of foot problems to your primary care provider. This is especially important for patients with diabetes.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

The patient's environment in a hospital or other facility consists of the bedside unit and the furnishings and equipment in the space around the bed. Basic furniture includes the bed, overbed table, bedside stand, and chairs. Standard equipment in the health care environment includes the call light, oxygen, suction, and electrical outlets; light fixtures; bath basin; emesis basin; bedpan or urinal; water pitcher and glass; and bed linens. One nursing responsibility is ensuring that necessary equipment and items are in their proper place and functioning properly. Patients usually store personal items in the bedside stand. Always request permission from alert patients or family members before opening the stand to obtain the bath basin, lotion, or other items. When assisting with hygiene, respecting the patient's right to privacy and ownership of personal goods decreases the patient's sense of powerlessness.

Good ventilation in patient rooms is imperative to limit pathogens and unpleasant odors associated with body secretions and excretions; for example, urine, stool, vomitus, draining wounds, or body odors. Decrease odors by emptying bedpans, urinals, and emesis basins promptly. When the waste receptacle in the patient's room is used to dispose of soiled dressings or anything with a strong odor, be sure to remove the trash before leaving the room. Dispose of the trash according to facility policy. Room deodorizers may need to be used.

Patient preferences for room temperature often vary widely. Whenever possible, respect the patient's preference when determining the room temperature. In general, the room temperature should be between 68°F and 74°F (20°C and 23°C).

Many patients find it difficult to sleep in a health care facility. Patients are often disturbed frequently for assessment or treatment purposes. Care should be taken to reduce harsh lighting and noises whenever possible, although adequate lighting is necessary for all nursing procedures. Whenever possible, avoid carrying on conversations immediately outside the patient's room. Many patients find this stressful because the noise disturbs them and because they believe whatever is being said involves them.

Before leaving the bedside, get into the habit of saying to the patient, "Is there anything else I can do to make you more comfortable?" Checking with the patient communicates genuine caring and can correct for any oversights.

BED SAFETY AND COMFORT

Many people who are ill and hospitalized or receiving care in other health care environments, or are being cared for at home may spend a large portion of the day in bed, so the bed is an important part of the patient's environment. Nursing responsibilities include ensuring a safe and comfortable bed.

The typical hospital bed has a motorized frame in three sections, which allows the height of the bed to be raised or lowered and the head and foot to be adjusted. Know how to operate the bed and be ready to explain it to the patient. Bed positions are described in Chapter 34. The height of the entire bed is usually adjustable as well, allowing the height to be adjusted to a comfortable level for the patient to move in and out of the bed (Morse et al., 2015). The bed elevation can also be adjusted to a comfortable level for caregivers to provide patient care. If the bed is elevated for any reason, for patient safety it is very important to place the bed in the lowest position after care is completed.

Bed size is an important consideration. Bed space must be sufficient to provide for patient comfort. Bed space must also be sufficient to allow for patient repositioning and participation in an almost unlimited number of care activities, such as wound inspection, dressing changes, cleaning or bathing, and linen changes. Research by Wiggermann et al. (2017) suggests BMI is a good predictor of the space required to turn from supine to lateral and provides guidance for choice of bed size for patients. Nurses should consider placing patients that are unable to laterally reposition themselves on a wider bed when the patient's BMI is greater than 35 kg/m^2 (Wiggerman et al., 2017). Patients with a BMI greater than 45 kg/m^2 should be placed on wider beds regardless of mobility (Wiggerman et al., 2017).

Newer bed designs include features to address patient satisfaction, patient safety, and caregiver efficiency (Wiggerman et al., 2019). For example, beds are available with frame designs that adjust for width and length of the patient and minimize patient migration (Ghersi et al., 2018; Wiggerman et al., 2019); lighted side rail handgrips to aid in visualization of bed rails when getting in and out of bed (Wiggerman et al., 2019); bed exit alarms and alarms that rearm when the patient returns to bed (Ghersi et al., 2018; Wiggerman et al., 2019); attachment points for the patient call bell to prevent it from falling out of reach (Wiggerman et al., 2019); and built-in USB ports so patients can charge personal electronic devices (Wiggerman et al., 2019).

Hospital beds can also be ordered for use in the home or other community-based care environments. Because certain positions may be harmful to some patients, instruct the patient and family/caregivers about advisable bed positions and the use of the bed controls. Side rails are used to provide assistance with moving in bed and movement in and out of bed (FDA, 2017a; Morse et al., 2015). Access to bed controls and is often on or in the side rails. See Chapter 28 for additional discussion about the use of side rails. Use side rails when indicated and according to facility policy. Also, lock the wheels or casters on the hospital bed whenever the bed is stationary to prevent the bed from moving when the patient is moving from the bed to an upright position or being transferred (FDA, 2017a). The headboard of most hospital beds is removable to allow close patient contact in an emergency situation.

Nurses are responsible for ensuring the safety and comfort of the patient at the bedside. To promote bed safety while maintaining patient comfort, ensure the following before leaving the patient's bedside:

- The bed is in its lowest position (FDA, 2017a). Low beds should be raised to the appropriate height for each patient to allow safe transition in and out of bed (Hester, 2015; Morse et al., 2015).

- The bed position is safe for the patient.
- The bed controls are functioning (bed is electrically safe).
- The call light is functioning and always within reach.
- Side rail(s) is/are raised if indicated or requested by the patient.
- The wheels or casters are locked (FDA, 2017a).

The hospital mattress is firm and generally covered with a water-repellent material that can be easily wiped with a bactericidal solution between patients. A variety of therapeutic beds and mattresses are available to reduce or relieve the effects of pressure on the skin (Fig. 32-6). These are discussed in more detail in Chapter 33. Other special beds are available for use in the care of patients with specific health issues, such as spinal injuries. Bariatric patient beds are extra-wide and designed to be used for patients who are very obese.

Facility policies usually dictate the availability and use of bed linens. Bed linens include mattress covers, sheets, incontinence pads, pillowcases, blankets, and bath blankets. Changing the bed linen is often not the nurse's responsibility and may be delegated. The nurse is responsible for coordinating with assistive personnel to ensure patient comfort. To promote bed comfort, ensure the following before leaving a patient:

- Linens are clean and free of crumbs and wrinkles.
- The patient feels comfortably warm.

FIGURE 32-6. This special bed is an air-flotation, low–air-loss support surface to aid in prevention and support treatment of pressure injury; support treatment of severe or extensive burns, skin flaps and grafts; and as part of pain management, with a lateral turn and hold to assist in repositioning the patient. (*Source:* Image of Citadel® Patient Care System used with permission of Arjo Inc.)

Through the Eyes of a Student

One of my first patients was a man in his late 60s who had suffered a stroke. I was assigned to care for him, and his care included a bed bath and complete linen change—with him in the bed. I was determined to complete this task totally on my own, without asking anyone for help. This was my first mistake.

The patient yelled out a lot and had very rough mannerisms. I kept thinking to myself, "I must treat him with gentle care and not show any fear." Inside I was shaking furiously.

I managed to complete his bath and then began to change the sheets. I helped the patient to turn to one side, tucking the dirty linens close to him. I applied the fitted sheets to the upper portion of the bed … so far, so good. Immediately going to the foot of the bed, I applied the bottom portion. The top portion popped off—I ran to the top of the bed, reapplied the top portion—the bottom portion popped off—I reapplied it…. I must have spent 15 minutes running back and forth trying to get both ends to stay on. By this time, sweat was pouring off my face.

When I finally cried "Uncle," I discovered that certain fitted sheets just didn't fit all the mattresses. The usual routine in this case is to walk to the linen closet and get another fitted sheet. That probably takes about 15 seconds!

—Linda A. Keough; Delaware County Community College, Media, Pennsylvania

- Pressure areas are protected from rough sheets and water-repellent materials. This is especially important for patients with an increased risk for impaired skin integrity.

MAKING A BED

A comfortable bed and appropriate bedding contribute to a patient's sense of well-being. Bed linens are changed after

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

the bath if the patient is bathed in the bed. Otherwise, many facilities change linens only when soiled. One method to change bed linen while the patient is out of the bed is described in Skill 32-4 on page 1134. A method to change bed linen with the patient in the bed is described in Skill 32-5 on page 1137.

Although there are variations in the procedure for making an occupied bed, these minor differences have no real effect on the patient's comfort. In some instances, creativity and flexibility are necessary when changing linens because of the patient's condition, orthopedic appliances on the bed, or treatments that may be in progress. Refer to Through the Eyes of a Student.

Teaching Patients About Skin Care

Teaching about skin care can occur at different times. For example, teaching can be done informally during assessment and personal care procedures. Here, the nurse shares information about general skin care measures, including ways to prevent or reduce a patient's risk for skin problems. Teaching addressing a specific topic, such as dry skin, diabetic foot care, or acne, may be addressed as part of the plan of care. The following section describes common topics related to skin care and skin problems.

SOAPS AND SKIN CLEANSERS

A wide variety of soaps and detergents are available. Soaps are often made from vegetable and animal fats, whereas most detergents are made from petroleum derivatives. For the most part, expensive cleansing agents are no more effective than their less expensive counterparts. Patients who experience dry skin or other alterations in skin health may benefit from using nonsoap skin cleansers. Refer to the discussion of these agents earlier in this chapter in the Promoting Skin Health section on page 1102.

DEODORANTS AND ANTIPERSPIRANTS

Perspiration is essentially odorless, although it contains some waste products, such as uric acid and ammonia. The odor of perspiration results when bacteria, normally present on everyone's skin, act on the skin's normal secretions.

Inform patients that keeping the body and clothing clean is the best way to prevent body odors. Recommend the use of deodorants and antiperspirants after the skin is clean. Deodorants eliminate odor by altering the pH of the skin to be more acidic, making it less attractive to bacteria (MFMER, 2019e). Antiperspirants contain aluminum-based compounds that temporarily block sweat pores, reducing the amount of perspiration that reaches the skin (MFMER, 2019e). Advise patients to use antiperspirants and deodorants with care and according to directions to prevent skin irritation. Keep in mind that these products are contraindicated in some situations; for example, before mammography and during the postoperative period for a patient who has a surgical wound under the arm, such as with a mastectomy.

COSMETICS

Cosmetics may be used to enhance the appearance of clean and healthy skin. Cosmetics may be used judiciously to help disguise blemishes, improve skin coloring, and make wrinkles appear less obvious. Some cultural and religious groups, however, may discourage their use.

Periodically, cosmetics containing harmful ingredients have appeared on the market. Be alert to such agents and help consumers avoid their use. The U.S. Department of Health and Human Services Food and Drug Administration (FDA) enforces federal laws on the purity of foods, drugs, and cosmetics and on the advertising claims of their manufacturers. The FDA is a good source of information regarding cosmetic safety. For example, the FDA maintains a list of color additives approved for use in cosmetics; encourage patients to check the ingredients of cosmetics, including color additives (FDA, 2017b).

Remind patients that cosmetics often become contaminated with bacteria and fungi. Teach patients not to share cosmetics and advise them to discard cosmetics after they are 2 to 4 months old, especially those applied near the eyes (FDA, 2016a). Encourage patients to keep makeup applicators and brushes immaculately clean.

SUNSCREEN

Spending time in the sun increases the risk of skin cancer and early skin aging (FDA, 2019b). Sun damage to the body is caused by invisible ultraviolet (UV) radiation. Patients of all skin tones are potentially at risk for sunburn and other harmful effects of exposure to UV radiation (FDA, 2019b). Everyone should take precautions to protect skin from sun damage. However, people who need to be especially careful in the sun are those who have pale skin; blond, red, or light brown hair; those who have been treated for skin cancer; or those who have a family member who's had skin cancer (FDA, 2019b). Others who need to be especially aware of sun-care precautions are patients who are prescribed certain medications that increase sun sensitivity, such as furosemide, glyburide, and quinolone antibiotics (e.g., ciprofloxacin). To reduce risk of sunburn and skin damage related to sun exposure, encourage patients to use sun protection measures. Refer to Box 32-4 for a list of suggested sun protection measures.

Box 32-4 Sun Protection Measures

Patients of all skin tones are potentially susceptible to sunburn and other harmful effects of exposure to UV radiation from the sun. Everyone should take precautions to protect skin from sun damage. To reduce risk of sunburn and skin damage related to sun exposure, encourage patients to use the following sun protection measures:

- Use broad-spectrum sunscreens with sun protection factor (SPF) values of 15 or higher regularly and as directed. Apply 15 minutes before you go outside for maximum benefit.
- Reapply sunscreen, even if labeled "water resistant," at least every 2 hours. Apply sunscreen more often if sweating, swimming, or jumping in and out of the water. Refer to individual product directions.
- Limit time in the sun, especially between the hours of 10 AM and 2 PM, when the sun's rays are most intense.
- Wear clothing to cover skin exposed to the sun; for example, long-sleeved shirts, pants, sunglasses, and broad-brimmed hats.
- Protect eyes with sunglasses. Choose sunglasses labeled with a UVA/UVB rating of 100%.
- Avoid using sunscreen for infants less than 6 months old. Keep infants under 6 months old out of the sun and in the shade. Dress infants in clothing that covers their sensitive skin, as well as a wide-brimmed hat.

(2016, July 6). *Should you put sunscreen on infants? Not usually*. https://www.fda.gov/consumers/consumer-updates/should-you-put-sunscreen-infants-not-usually

TICKS

Ticks are a significant problem because they can transmit serious diseases such as Lyme disease, Rocky Mountain spotted fever, and Colorado tick fever. Ticks attach themselves to a human host as the person brushes past leaves, brush, and tall grasses. Once on a person, ticks move to a warm and moist location, like the hairline, armpit, or groin, where they burrow into the host's skin and feed off the host's blood. Transmission of tick-borne diseases can be decreased if the tick is removed within 24 hours of becoming attached. To remove a tick, grasp it with clean fine-tipped tweezers close to the skin. Pull upward with steady, even pressure; do not twist or jerk the tick (CDC, 2019b). If mouth-parts break off and remain in the skin, remove the mouth-parts with the tweezer (CDC, 2019b). Once the tick is removed, cleanse the bite area and your hands with rubbing alcohol or soap and water (CDC, 2019b). Dispose of a live tick by putting it in alcohol, placing it in a sealed bag, wrapping tightly in tape, or flushing down the toilet (CDC, 2019b). A person should seek medical attention if a rash or fever develops within several weeks of removing a tick.

Information related to the prevention of tick bites is an important focus of patient education. Encourage patients to wear long sleeves, long pants, and long socks to help prevent ticks from coming in contact with the skin. Patients should apply insect repellent on clothing (permethrin) and exposed skin (product with at least 20% DEET) (National Institutes of Health [NIH], 2014). Clothing and skin should be checked frequently for ticks, which look like small black or brown spots. Encourage patients to bathe or shower as soon as possible after activities in an area where ticks are common and wash and/or dry clothes in a dryer on high heat (NIH).

Evaluating

Performing or assisting with the performance of hygiene measures provides a means of at least daily contact with the patient to determine whether the patient is achieving outcomes related to hygiene and skin care. Indicators that can be used to determine outcome achievement include the following:

- Level of patient's participation in hygiene program
- Elimination of, reduction in, or compensation for factors interfering with the patient's independent execution of hygiene measures; for example, weakness, decreased motivation, and lack of knowledge
- Changes related to specific skin problems; for example, healing of skin lesions, elimination or reduction in causative factors, and independent patient management of the prescribed treatment program

Ongoing evaluation helps adjust the plan of care. Refer to the accompanying Nursing Care Plan 32-1 (on pages 1118–1120) for Kylie Simpson and Female University Students for examples of the nursing process related to hygiene.

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the goal of reflective practice is to look at an experience, understand it, and learn from it. As you begin

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

to develop expertise in implementing hygiene measures, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following while performing hygiene measures and providing nursing care:

- Did your commitment to engage your patients and families and to collaborate with your fellow students, instructor, and other members of the health care team as you implemented the plan of care result in successful partnerships?
- Did your preparation and practice related to performing interventions related to hygiene result in your feeling confident in your ability to provide care? Did your competence and confidence inspire the patient's and family's trust?
- How did you prioritize the data you collected? What patterns in the data did you identify? What knowledge from your learning, personal experience, and intuition did you use to make decisions and develop your plan of care?
- How confident are you that the data you reported and recorded accurately communicates the health status, health problems, issues, risks, and strengths of the patient? How successfully have you communicated this information to other members of the health care team?
- Were you aware of any cultural and/or ethnic beliefs or practices that may have influenced the patient's personal hygiene practices? Were you aware of any stereotypes or prejudices that might have negatively influenced the clinical encounter? If so, how did you address these issues?
- Did you need to modify the plan of care as a result of ongoing assessments? Did you think of better interventions to produce the expected outcomes?
- As you concluded your patient interactions, did the patient/family know your name, and know what to expect of you and your nursing care? Did the patient sense that you are respectful, caring, and competent to provide care?

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to address their hygiene needs? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Nursing Care Plan for *Kylie Simpson and University Students 32-1*

Glenda Davis is a nurse practitioner who works in a campus health clinic at a state university. Kylie Simpson met with Glenda Davis at the clinic. Kylie had been having vaginal itching and burning for 2 weeks. She was diagnosed with a vaginal infection. She asks Glenda, "This is terrible. It's the second infection in 7 months. Is there something wrong with me? Isn't there something I can do to keep this from happening again?"

Frequently, students ask Glenda questions about personal hygiene. Realizing that each student who presents with a question probably represents many other students with similar unvoiced questions, Glenda talks with Kylie, including patient teaching regarding personal hygiene and sexual health in their discussion. Glenda decides to develop an insert entitled *Self-Care: Personal Hygiene/Sexual Health* for the campus newspaper. The information she plans to include and the population she will address in her checklist are based on the following assessment data:

- Diverse population of various ages, cultures, religions, gender identities, sexual orientation, and family and lifestyle backgrounds.
- Knowledge about personal hygiene/sexual health varies widely from almost no knowledge to students who are well read or members of health professions.
- Students who present with questions are mostly concerned about the risk of acquiring a sexually transmitted infection (STI) or the dangers of certain products (e.g., tampons and toxic shock syndrome), or have questions related to intercourse and contraception.
- Numerous students report to the clinic with vaginal infections and urinary tract infections.
- Interest is high; ability to comprehend written materials is high.

HEALTH PROBLEM/NEED	Knowledge Deficiency: Personal hygiene/sexual health

EXPECTED OUTCOME	Etiology: Information misinterpretation, lack of exposure, and unfamiliarity with information resources Signs/Symptoms: Students presenting to the campus clinic with questions about personal hygiene/sexual health; high incidence of vaginal and urinary tract infections; negative attitudes about body frequently expressed Students will: • express positive body image, valuing their uniqueness.

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
With each student who presents at the clinic for help with a gynecologic/sexual health concern or problem, take the time to assess their knowledge of the body and acceptance of their body and comfort with it.	The sexual health movement has encouraged feelings of ownership of their bodies, to appreciate their uniqueness, and to increase their awareness of their physical bodies and the feelings associated with them. Students may still feel that the genital area and cyclic phenomena such as the menstrual cycle and the sexual response cycle are "dirty"; and symptoms in this area may evoke fear, guilt, anxiety, and shame.	*Six-month evaluation:* 6/30/25 Outcome partially met: Students are beginning to discuss personal and sexual health concerns more freely, yet great hesitance persists. *G. Davis, RN*
Revision: Continue to help students to know, understand, and accept their bodies and to talk about their bodies. Make this a priority of the nursing staff at the clinic.		
Counsel appropriately.	It is important for nurses to provide students with information about their bodies.	

EXPECTED OUTCOME	Students will: • correctly describe hygiene self-care behaviors they are willing to incorporate into their daily lifestyles.

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Assess with each patient their knowledge of hygiene practices (correct any misconceptions) and motivation to use them consistently.	Many women have never been instructed about hygiene, and harmful practices may be "picked up" from the media and other sources (e.g., the use of frequent douching and deodorants to eliminate normal body odors).	6/30/25 Outcome met. Following publication of the *Self-Care: Feminine Hygiene* feature and one-on-one counseling using this printed handout, patients are knowledgeable about preventive hygiene measures. *G. Davis, RN*
Address specific concerns related to menstruation, intercourse, sexual health, other	Maturational events, such as menstruation, becoming sexually active, and pregnancy, may	

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

maturational events.	result in a need for new or modified hygiene practices.
Teach the importance of using preventive hygiene measures to reduce the likelihood of acquiring a urinary tract or vaginal infection. Distribute the *Self-Care: Personal Hygiene/Sexual Health* handout and discuss this with the patient.	It is better to prevent a genitourinary infection than to treat it.

EXPECTED OUTCOME

Campus health clinic records will:

- demonstrate a reduction in both new and recurrent genitourinary infections.

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Educate students regarding preventive hygiene measures (refer to the *Self-Care* handout).	It is better to prevent a genitourinary infection than to treat it.	6/30/25 Outcome met. Six months after publication and use of the *Self-Care: Personal Hygiene/Sexual Health* handout, the incidence of genitourinary infections is reduced 10%. Will continue to keep education in this regard a priority. *G. Davis, RN*
Educate students to distinguish normal from abnormal findings (vaginal discharge, pain, bleeding, problems with urination) and to seek help when appropriate. Nursing measures include teaching preventive measures, instructing in recognition of symptoms, and assisting with self-care activities to prevent and treat infections, including the securing of assistance when indicated.	Early treatment of genitourinary infections reduces the likelihood of residual problems.	
Document new and recurrent genitourinary infections; identify predisposing factors.	Documentation facilitates ongoing management of a recurring problem.	

SAMPLE DOCUMENTATION

6/15/25

Nursing student visited clinic and expressed need for information about feminine hygiene practices in general as well as those specific hygiene measures for use after intercourse. Also related concern about contracting an STI from partners. Reported that she became sexually active this year and has sexual intercourse once or twice weekly. Stated that "many of my friends use douches" and questioned whether any particular douche products are recommended. Discussed the *Self-Care: Feminine Hygiene* handout and reviewed various health care practices. Clarified for student her misconception regarding the advisability of douching. Also counseled her about her right to talk with a sexual partner about STIs and previous contacts with infected people. Advised that she refrain from contact or use a condom when she has intercourse. Student reported feeling more "in charge" of body and better able to care for it. Discussed all topics on care plan and encouraged her to revisit clinic in 6 months for further clarification and evaluation.

G. Davis, RN

Skill 32-1

Providing a Bed Bath

DELEGATION CONSIDERATIONS

The implementation of a bed bath may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Washbasin and warm water
- Personal hygiene supplies (deodorant, lotion, and others)
- Skin-cleaning agent
- Emollient and skin barrier, as indicated
- Towels (2)
- Washcloths (2)
- Bath blanket
- Gown, pajamas, or appropriate clothing
- Bedpan or urinal
- Laundry bag
- Nonsterile gloves; other PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for any limitations in physical activity.	Identifying limitations prevents patient discomfort and injury.
 2. Perform hand hygiene and put on gloves and/or other PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient. Discuss the procedure with the patient and assess the patient's ability to assist in the bathing process, as well as personal hygiene preferences.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors. Discussion promotes reassurance and provides knowledge about the procedure. Dialogue encourages patient participation and allows for individualized nursing care.
4. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.
5. Close the curtains around the bed and close the door to the room, if possible. Adjust the room temperature, if necessary.	This ensures the patient's privacy and lessens the risk for loss of body heat during the bath.
6. Adjust the bed to a comfortable working height (VHA Center for Engineering & Occupational Safety and Health [VHACEOSH], 2016).	Having the bed at the proper height prevents back and muscle strain.
7. Remove sequential compression devices and graduated compression (antiembolism) stockings from lower extremities according to facility protocol.	Most manufacturers and facilities recommend removal of these devices before the bath to allow for assessment.
8. Put on gloves. Offer the patient a bedpan or urinal.	Gloves are necessary for potential contact with blood or body fluids. Voiding or defecating before the bath lessens the likelihood that the bath will be interrupted, because warm bath water may stimulate the urge to

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	void.
 9. Remove gloves and perform hand hygiene.	Hand hygiene deters the spread of microorganisms.
10. Put on a clean pair of gloves. Lower the side rail nearest to you and assist the patient to the side of bed where you will work. Have the patient lie on their back.	Gloves prevent transmission of microorganisms. Having the patient positioned near the nurse and lowering the side rail prevent unnecessary stretching and twisting of muscles on the part of the nurse.
11. Loosen top covers and remove all except the top sheet. Place a bath blanket over the patient and then remove the top sheet while the patient holds the bath blanket in place. If linen is to be reused, fold it over a chair. Place soiled linen in laundry bag. Take care to prevent linen from coming in contact with your clothing.	This ensures that the patient is not exposed unnecessarily, and warmth is maintained. If a bath blanket is unavailable, the top sheet may be used in its place.
12. Remove the patient's gown or clothing and keep the bath blanket in place. If the patient has an IV line and is not wearing a gown with snap sleeves, remove gown from the other arm first. Pause the infusion pump and remove the tubing from the pump. Lower the IV container and pass the gown over the tubing and the container. **Rehang the IV container and insert the tubing into the infusion pump. Check the rate on the infusion pump and restart.**	This provides uncluttered access during the bath and maintains warmth of the patient. IV fluids must be maintained at the prescribed rate.
13. **Raise side rails and lower the bed.** Fill basin with a sufficient amount of comfortably warm water (no more than 120°F [49° C]). Add the skin cleanser, if appropriate, according to the manufacturer's directions. Change, as necessary, throughout the bath.	Side rails and lower bed height maintain patient safety. Adjusting the water temperature to no more than 120°F (49° C) decreases risk of burns and drying of the skin (International Association of Fire Fighters [IAFF], n.d.). Warm water is comfortable and relaxing for the patient. It also stimulates circulation and provides for more effective cleansing.
14. Raise the bed to a comfortable working height and lower the side rail nearest to you when you return to the bedside to begin the bath. Put on gloves, if indicated. Lay a towel across the patient's chest and on top of bath blanket.	Having the bed at the proper height prevents back and muscle strain. Gloves are necessary if there is potential contact with blood or body fluids. The towel prevents chilling and keeps the bath blanket dry.
15. With no cleanser on the washcloth, wipe one eye from the inner part of the eye, near the nose, to the outer part (Figure 1). Rinse or turn the cloth before washing the other eye.	Cleanser may be irritating to the eyes. Moving from the inner to the outer aspect of the eye prevents carrying debris toward the nasolacrimal duct. Rinsing or turning the washcloth prevents spreading organisms from one eye to the other.
16. Bathe the patient's face, neck, and ears. Apply appropriate emollient.	Use of emollients is recommended to restore and maintain skin integrity (Haesler et al., 2018; Lichterfeld et al., 2015; Voegeli, 2019).
17. Expose the patient's far arm and place towel lengthwise under it. Using firm strokes, wash hand, arm, and axilla, lifting the arm as necessary to access axillary region (Figure 2). Rinse, if necessary, and dry. Apply appropriate emollient. Cover the area with the bath blanket.	The towel helps to keep the bed dry. Washing the far side first eliminates contaminating a clean area once it is washed. Gentle friction stimulates circulation and muscles and helps remove dirt, oil, and organisms. Long, firm strokes are relaxing and more comfortable than short, uneven strokes. Rinsing is necessary when using some cleansing products. Use of emollients is recommended to restore and maintain skin integrity (Haesler et al., 2018; Lichterfeld et al., 2015; Voegeli, 2019). Re-covering the body maintains warmth.

FIGURE 1. Washing from the inner corner of the eye outward.

FIGURE 2. Exposing the far arm and washing it.

18.	Repeat Step 17 for the arm nearest you. Another option might be to bathe one side of the patient first and then move to the other side of the bed to complete the bath.	
19.	Spread a towel across the patient's chest. Lower the bath blanket to the patient's umbilical area. Wash, rinse, if necessary, and dry chest. Keep chest covered with towel between the wash and rinse. Pay special attention to the folds of skin under the breasts. Apply appropriate emollient.	Exposing, washing, rinsing, and drying one part of the body at a time avoids unnecessary exposure and chilling. Areas of skin folds may be sources of odor and skin breakdown if not cleaned and dried properly. Use of emollients is recommended to restore and maintain skin integrity (Haesler et al., 2018; Lichterfeld et al., 2015; Voegeli, 2019).
20.	Lower the bath blanket to the perineal area. Place a towel over the patient's chest.	Keeping the bath blanket and towel in place avoids exposure and chilling.
21.	Wash, rinse, if necessary, and dry abdomen (Figure 3). Carefully inspect and clean umbilical area and any abdominal folds or creases. Apply appropriate emollient.	Skin-fold areas may be sources of odor and skin breakdown if not cleaned and dried properly. Use of emollients is recommended to restore and maintain skin integrity (Haesler et al., 2018; Lichterfeld et al., 2015; Voegeli, 2019).
22.	Return bath blanket to original position and expose far leg. Place towel under far leg. Using firm strokes, wash, rinse, if necessary, and dry leg from ankle to knee and knee to groin (Figure 4). Apply appropriate emollient.	The towel protects linens and prevents the patient from feeling uncomfortable from a damp or wet bed. Washing from ankle to groin with firm strokes promotes venous return. Use of emollients is recommended to restore and maintain skin integrity (Haesler et al., 2018; Lichterfeld et al., 2015; Voegeli, 2019).

FIGURE 3. Washing the abdomen, with perineal and chest areas covered.

FIGURE 4. Washing and drying far leg, keeping the other leg covered.

23.	Wash, rinse if necessary, and dry the foot. Pay	Drying of the feet is important to prevent irritation,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	particular attention to the areas between toes. Apply appropriate emollient.	possible skin breakdown, and infections (Beuscher, 2019). Use of emollients is recommended to restore and maintain skin integrity (Haesler et al., 2018; Lichterfeld et al., 2015; Voegeli, 2019).
24.	Repeat Steps 22 and 23 for the other leg and foot.	
25.	Make sure the patient is covered with the bath blanket. Change water and washcloth at this point or earlier, if necessary.	The bath blanket maintains warmth and privacy. Clean, warm water prevents chilling and maintains patient comfort.
26.	Assist the patient to a prone or side-lying position. Put on gloves, if not applied earlier. Position bath blanket and towel to expose only the back and buttocks.	Positioning the towel and bath blanket protects the patient's privacy and provides warmth. Gloves prevent contact with body fluids.
27.	Wash, rinse, if necessary, and dry back and buttocks area (Figure 5). **Pay particular attention to cleansing between gluteal folds and observe for any redness or skin breakdown in the sacral area.**	Fecal material near the anus may be a source of microorganisms. Prolonged pressure on the sacral area or other bony prominences may compromise circulation and lead to development of decubitus ulcer.

FIGURE 5. Washing the back.

28.	If not contraindicated, give the patient a backrub. Alternatively, back massage may be given after perineal care. Apply appropriate emollient and/or skin barrier product.	A backrub improves circulation to the tissues and is an aid to relaxation. A backrub may be contraindicated in patients with cardiovascular disease or musculoskeletal injuries. Use of emollients is recommended to restore and maintain skin integrity (Haesler et al., 2018; Lichterfeld et al., 2015; Voegeli, 2019). Skin barriers protect the skin from damage caused by excessive exposure to water and irritants, such as urine and feces (Williamson, 2020; Voegeli, 2019).
29.	Remove gloves. Raise the side rail. Refill basin with clean water. Discard washcloth and towel. Put on clean gloves.	The washcloth, towel, and water are contaminated after washing the patient's gluteal area. Changing to clean supplies decreases the spread of organisms from the anal area to the genitals.
30.	Set the patient up so they can complete perineal self-care. If the patient is unable to complete self-care, lower the side rail and complete perineal care. Apply skin barrier, as indicated. Raise the side rail, remove gloves, and perform hand hygiene.	Providing perineal self-care may decrease embarrassment for the patient. Effective perineal care reduces odor and decreases the risk for infection through contamination. Skin barriers protect the skin from damage caused by excessive exposure to water and irritants, such as urine and feces.
31.	Help the patient put on a clean gown or clothing and assist with the use of other personal toiletries, such as deodorant or cosmetics. If the gown does not have	This provides for the patient's warmth and comfort.

snap sleeves and the patient has an IV, follow the steps in Action 12 to replace the gown.

32. Protect pillow with towel, and groom the patient's hair.

33. **When finished, make sure the patient is comfortable, with the side rails up and the bed in the lowest position.**

Proper positioning with raised side rails and proper bed height provides for patient comfort and safety.

34. Change bed linens, as described in Skills 32-4 and 32-5. Dispose of soiled linens according to facility policy. Clean bath basin according to facility policy before returning to storage at bedside. Remove gloves and any other PPE, if used. Perform hand hygiene.

Proper disposal of linens and cleaning of bath basin reduce the risk for transmission of microorganisms. Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Record any significant observations and communication. Document the condition of the patient's skin. Record the procedure, amount of assistance given, and patient participation. Document the application of skin care products, such as a skin barrier.

Sample Documentation

07/06/2025 2130 Bath provided with complete assistance; reddened area (3 cm × 3 cm) noted on patient's sacral area; skin-care team consultation made.

—C. Stone, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient becomes chilled during the bath:* If the room temperature is adjustable, increase it. Another bath blanket may be needed.
- *Patient becomes unstable during the bath:* Critically ill patients may need to be bathed in stages. For instance, the right arm is bathed, and then the patient is allowed to rest for a short period before the left arm is bathed. The amount of rest time needed depends on how unstable the patient is and which parameter is being monitored. For example, the nurse may watch the blood pressure while bathing an unstable patient and stop when it begins to decrease. Once the blood pressure returns to the previous level, the nurse can begin to bathe the patient again.

SPECIAL CONSIDERATIONS

General Considerations

- To remove the gown without snap sleeves from a patient with an IV line, take the gown off the uninvolved arm first, then pause the infusion pump and remove the tubing from the pump. Lower the IV container and pass the gown over the tubing and the container. **Rehang the IV container and insert the tubing into the infusion pump. check the rate on the infusion pump and restart.** To replace the gown, follow the same steps, placing the clean gown on the unaffected arm first. **Never disconnect IV tubing to change a gown, because this causes a break in a sterile system and could introduce microorganisms**.
- Patients with bariatric care needs are at increased risk for skin integrity issues, including increased risk for alterations in skin integrity (Earlam & Woods, 2020; Williamson, 2020). Assess the skin of bariatric inpatients twice a day, lifting and separating the folds of skin to assess the area, utilizing extra help as necessary (Black & Hotaling, 2015). Nonsoap cleansers should be used, and the skin should be dried to prevent retained moisture (Black & Hotaling, 2015; Williamson, 2020).
- When bathing a patient, the wipe or washcloth removes some of the outermost skin layer. This sloughed skin may be evident on the wipe or washcloth and in the bathwater and will vary in color depending on the ethnic group of the patient (Andrews et al., 2020). This is important to note, as this does not mean that the patient was dirty—the normal sloughing of the skin is more evident in darkly pigmented people compared with patients with lighter pigmentation (Andrews et al., 2020).
- Lying flat in bed during the bed bath may be contraindicated for certain patients. The position may have to be

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

modified to accommodate their needs.

- Incontinent patients require special attention to perineal care. Patients with urinary or fecal incontinence are at risk for incontinence-associated dermatitis (perineal dermatitis), one type of moisture-associated skin damage (MASD) (Voegeli, 2019). Remove soil and irritants from the skin during routine hygiene as well as cleansing when the skin becomes exposed to irritants (Voegeli, 2019). Avoid using soap and excessive force for cleaning (Wounds UK, 2018). Use perineal skin cleansers, moisturizers, and moisture barriers for skin care for these patients to promote healing and prevent further skin damage (Voegeli, 2019).
- If the patient has an indwelling catheter, use mild soap and water or a perineal cleanser to clean the perineal area; rinse the area well. Do not clean the periurethral area with antiseptics to prevent CAUTI while the catheter is in place (Gould et al., 2019). Routine hygiene (cleansing of the meatal surface during daily bathing or showering) is appropriate (Gould et al., 2019). Inspect the meatus for drainage and note the characteristics of the urine. Do not use powders and lotions after cleaning.
- The use of chlorhexidine gluconate (CHG) for bathing has been shown to reduce colonization of skin with pathogens and is an important measure utilized by institutions in an attempt to decrease health care–associated infections (HAIs), such as central line–associated bloodstream infections and surgical site infections (Hines et al., 2015; Martinez et al., 2020; Musuuza et al., 2019; Urias et al., 2018). Some facilities' policies include the use of CHG for all inpatient bathing, expect for patients with a history of CHG allergy or intolerance or those age less than 2 months (Hines et al., 2015). Chlorhexidine can be added to bath water but is also available in prepackaged impregnated cloths.
- If applying lotion, warm the lotion in your hands before applying it to the patient to prevent chilling.
- Soaking the patient's hands in a basin of water is an additional comfort measure for the patient. It facilitates thorough washing of the hands and between the fingers and aids in removing debris from under the nails. If appropriate and as indicated, place a folded towel on the bed next to the patient's hand and put the basin of water on it. Wash, rinse if necessary, and dry hand. Apply appropriate emollient. Use of emollients is recommended to restore and maintain skin integrity (Haesler et al., 2018; Lichterfeld et al., 2015; Voegeli, 2019).
- Basic wound care used for body piercings is usually called "aftercare." Aftercare techniques are used for the new piercing and whenever the piercing fistula has become disrupted through injury or exhibits signs of infection or inflammation (Association of Professional Piercers, 2020; Mayo Foundation for Medical Education and Research, 2020b). Clean the site with mild soap and warm water or normal saline solution (American Academy of Family Physicians, 2019). Use a cotton swab to gently remove any crusting. Rinse well.

Infant and Child Considerations

- When bathing an infant or young child, have supplies within easy reach, and support or hold the child securely at all times to ensure safety.
- Never leave the child alone.
- Consider bathing a newborn using a reverse-order procedure, from "trunk to head," wetting the infant's head last to reduce the amount of time the infant's head is wet. The method supports a more rapid recovery of body temperature and decreased heat loss from evaporation during bathing (So et al., 2014).
- Delaying the newborn bath for 24 hours has been associated with multiple benefits, including increased likelihood of exclusive breastfeeding at discharge and decreased incidence of hypothermia and hypoglycemia in healthy newborns (Warren et al., 2020).

Older Adult Considerations

- Check the temperature of the water carefully before bathing an older adult, because sensitivity to temperature may be impaired in older adults.
- An older continent patient may not require a full bed bath with soap and water every day. If dry skin is a problem, water and skin lotion or bath oil may be used on alternate days.

Community-Based Care Considerations

- Use plastic trash bags or a plastic shower-curtain liner to protect the mattress when bathing or shampooing a patient in bed. Disposable washcloths may also be an option to consider. A large plastic container or baby bathtub can effectively serve as a shampoo basin.
- If linens are soiled with blood or body fluids, instruct family members/caregivers to wear gloves when handling them. The linens should be rinsed first in cold water and then washed separately from other household wash, using hot water, laundry detergent, and bleach.
- Teach a family member or caregivers how to perform comfort measures, such as a backrub.
- If patients are home with an indwelling catheter, instruct them or their caregivers to wash the urinary meatus and perineal area with mild soap and water.

Skill 32-2

Assisting the Patient With Oral Care

DELEGATION CONSIDERATIONS

The implementation of oral care may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Toothbrush
- Toothpaste
- Emesis basin
- Glass with cool water
- Disposable gloves
- Additional PPE, as indicated
- Towel
- Mouth rinse
- Washcloth or paper towel
- Lip lubricant (optional)
- Dental floss or other interdental cleaner
- Oral assessment tool, as indicated (Figure 1)

IMPLEMENTATION

ACTION	RATIONALE
 1. Perform hand hygiene and put on gloves if assisting with oral care, and/or other PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 2. Identify the patient. Explain the procedure to the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors. Explanation facilitates engagement in care.
3. Assemble equipment on the overbed table or other surface within the patient's reach.	Organization facilitates performance of the task.

Tongue	Normal, moist roughness, pink	Patchy, fissured, red, coated	Patch that is red &/or white, ulcerated, swollen						
Gums and tissues	Pink, moist, smooth, no bleeding	Dry, shiny, rough, red, swollen, one ulcer/sore spot under dentures	Swollen, bleeding, ulcers/white/red patches, generalized redness under dentures						
Saliva	Moist tissues, watery and free flowing saliva	Dry, sticky tissues, little saliva present, resident thinks they have dry mouth	Tissues parched and red, very little/no saliva present, saliva is thick, resident thinks they have a dry mouth						
Natural teeth Yes/No	No decayed or broken teeth/roots	1–3 decayed or broken teeth/roots or very worn down teeth	4+ decayed or broken teeth/roots, or very worn down teeth, or less than 4 teeth						
Dentures Yes/No	No broken areas or teeth, dentures regularly worn and labeled with name of resident	1 broken area/tooth or dentures only worn for 1-2 hours daily, or dentures not labeled with name, or loose	More than 1 broken area/tooth, denture missing or not worn, loose and needs denture adhesive or not labeled with name						
Oral cleanliness	Clean and no food particles or tartar in mouth or dentures	Food particles/tartar/ plaque in 1–2 areas of the mouth or on small area of dentures or halitosis (bad breath)	Food particles/tartar/plaque in most areas of the mouth or on most of dentures or severe halitosis (bad breath)						
Dental pain	No behavioral, verbal, or physical signs of dental pain	Verbal &/or behavioral signs of pain such as pulling at face, chewing lips, not eating, aggression	Physical pain signs (swelling of cheek or gum, broken teeth, ulcers), as well as verbal &/or behavioral signs (pulling at face, not eating, aggression)						
Total Score: _____				____ 16	____ 16	____ 16	____ 16	____ 16	____ 16

_____ Arrange for resident to have a dental examination by a dentist

_____ Resident and/or family/guardian refused dental treatment

_____ Complete Oral Hygiene Care Plan and start oral hygiene care interventions for resident

_____ Review this resident's oral health again on:_____

*If 1 or 2 scored for any category, please arrange for a dentist to examine the resident

Modified from Kayser-Jones et al., (1995) by Chalmers (2000b); Chalmers, King et al., (2005); Chalmers et al., (2004)

FIGURE 1. Oral Health Assessment Tool (OHAT). (Mouth Care Without a Battle, UNC Cecil G. Sheps Center for Health Services Research. Used by Permission.) *(continued)*

4. Close the room door or curtains. Place the bed at an appropriate and comfortable working height (VHACEOSH, 2016).	Closing the door or curtains provides privacy. Proper bed height helps reduce back strain while performing the procedure.
5. Lower the side rail and assist the patient to a sitting position, if permitted, or turn the patient onto their side. Place a towel across the patient's chest.	The sitting or side-lying position prevents aspiration of fluids into the lungs. The towel protects the patient from dampness.
6. Encourage the patient to brush their own teeth according to the following guidelines. Assist, if necessary.	
a. Moisten the toothbrush and apply toothpaste to bristles.	Water softens the bristles.
b. Place the brush at a 45-degree angle to gum line (Figure 2) and brush from gum line to crown of each tooth (Figure 3). Brush outer and inner	Facilitates removal of **plaque** and **tartar**. The 45-degree angle of brushing permits cleansing of all tooth surface areas.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

surfaces. Brush back and forth across the biting surface of each tooth.

c. Brush the tongue gently with toothbrush or tongue scraper (MFMER, 2019a) (Figure 4). — This removes coating on the tongue. Gentle motion does not stimulate the gag reflex.

d. Have the patient rinse vigorously with water and spit into emesis basin (Figure 5). Repeat until clear. Suction may be used as an alternative for removal of fluid and secretions from the mouth. — The vigorous swishing motion helps to remove debris. Suction is appropriate if the patient is unable to expectorate well.

FIGURE 2. Placing brush at a 45-degree angle to gum line.

FIGURE 3. Brushing from gum line to the crown of each tooth.

FIGURE 4. Brushing tongue.

FIGURE 5. Holding emesis basin for patient to rinse and spit.

7. Assist the patient to floss their teeth, if appropriate: — Flossing aids in removal of food and plaque and promotes healthy gum tissue (American Dental Association [ADA], n.d.b).

a. Remove approximately 18 inches of dental floss from container or use a plastic floss holder. Wrap most of the floss around one of the middle fingers. Wind the remaining floss around the same finger of the opposite hand, keeping about 1 to 1.5 inches of floss taut between the fingers. — The floss must be held taut to get between the teeth.

b. Insert floss gently between teeth, moving it back and forth downward to the gums. — Trauma to the gums can occur if floss is forced between teeth.

c. Move the floss up and down, first on one side of a tooth and then on the side of the other tooth, until the surfaces are clean (Figure 6). Repeat in the spaces between all teeth and the backside of — This ensures that the sides of both teeth are cleaned.

the last teeth.	
d. Instruct the patient to rinse mouth well with water after flossing.	Vigorous rinsing helps to remove food particles and plaque that have been loosened by flossing.

FIGURE 6. Flossing teeth.

8. Offer a mouth rinse if the patient prefers or if use has been recommended.	Use of a mouth rinse can reduce bacteria and can help reduce plaque, gingivitis, tartar (hardened plaque) and also freshen breath. Anticavity rinses with fluoride help protect tooth enamel to help prevent or control tooth decay (ADA, 2019).
9. Offer lip balm or petroleum jelly.	Lip balm lubricates lips and prevents drying.
10. Remove equipment. Remove gloves and discard. Perform hand hygiene. Raise the side rail and lower the bed. Assist the patient to a position of comfort.	Removing gloves properly reduces the risk for infection transmission and contamination of other items. These actions promote patient comfort and safety.
11. Remove any other PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Record oral assessment, significant observations, and unusual findings, such as bleeding or inflammation. Document any teaching done. Document procedure and patient response.

Sample Documentation

10/2025 0930 Patient performed oral care with minimal assistance. Oral cavity mucosa pink and moist. No evidence of bleeding or ulceration. Lips slightly dry; lip moisturizer applied. Reinforcement provided related to importance of flossing teeth every day. Patient demonstrates appropriate flossing technique.

—L. Schneider, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *While cleaning the teeth, you notice a large amount of bleeding from the gum line:* Stop brushing. Allow the patient to gently rinse mouth with water and spit into emesis basin. Before brushing again, check the patient's most recent platelet level. Consider the use of a softer toothbrush to provide oral hygiene.
- *Patient has braces on their teeth:* Braces collect food particles. Brush extra thoroughly. Reinforce the importance of using an appropriate interdental cleaner.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

SPECIAL CONSIDERATIONS

General Considerations

- Use a soft-bristled toothbrush with a small head even when the patient has no or few teeth. It is the only effective way to remove plaque and debris from the teeth, gums, and tongue.
- Automatic toothbrushes, electric or battery operated, are simple to use and can be used to removing debris and plaque and clean the teeth effectively. Use of an electric toothbrush provides superior oral hygiene care when oral hygiene is provided by a caregiver (Vannah & Sammarco, 2019).
- The use of chlorhexidine gluconate (CHG) as part of oral hygiene has been integrated into oral hygiene regimens and is available as an oral rinse, oral spray, and dental gel (AACN, 2017; de Camargo et al., 2019). The use of CHG as part of protocols for systematic oral care for critically ill patients has been shown to reduce risk of ventilator-associated pneumonia (VAP) (AACN, 2017; Chen et al., 2015).

Infant and Child Considerations

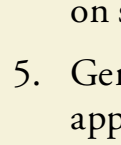
- Begin brushing children's teeth as soon as they begin to come into the mouth and begin flossing when the child has two teeth that touch (ADA, n.d.a).
- Clean an infant's gums by wiping with a clean, damp cloth (ADA, n.d.a).
- Young children should be supervised by an adult until they are between ages 7 and 10 years (Kyle & Carman, 2021); remind them not to swallow the toothpaste (ADA, n.d.a).
- Use smaller amounts of fluoride toothpaste on the toothbrush for children: a smear (size of a grain of rice) for children younger than age 3 years and a pea-sized amount for children ages 3 to 6 years (ADA, n.d.a).

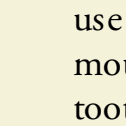
Older Adults

- Physical limitations that may be associated with aging may interfere with the older adult's ability to perform adequate oral hygiene (Thomas, 2019). Pressurized water spray units (water flossing) are available to assist with oral hygiene to and can be a useful option for older adults and other patients who have trouble flossing by hand (ADA, n.d.d).

Skill 32-3 Providing Oral Care for the Dependent Patient

DELEGATION CONSIDERATIONS





The implementation of oral care for a dependent patient may be delegated to assistive personnel (AP) after assessment by the registered nurse as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Suction toothbrush (see Figure 4) or soft toothbrush
- Suction swab
- Suction catheter with suction apparatus
- Toothpaste or other oral cleanser
- Emesis basin
- Glass with cool water
- Disposable gloves
- Additional PPE, as indicated
- Towel
- Mouth rinse (optional)
- Dental floss in holder or other interdental cleaner
- Mouth-prop or second toothbrush (Figure 1)
- Denture-cleaning equipment (if necessary)
- Denture cup
- Denture cleaner
- 4 × 4 gauze

- Washcloth or paper towel
- Lip lubricant (optional)
- Oral health assessment tool (see Figure 1 in Skill 32-2)
- Additional care giver, as indicated

IMPLEMENTATION

ACTION	RATIONALE
 1. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 2. Identify the patient. Explain the procedure to the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors. Explanation facilitates engagement in care.
3. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.
4. Close the room door or curtains. Place the bed at an appropriate and comfortable working height (VHACEOSH, 2016). Lower one side rail and position the patient on the side, with head tilted forward. Place towel across the patient's chest and emesis basin in position under chin. Depending on equipment in use, connect the suction toothbrush/swab or suction catheter to suction tubing and turn on suction. Put on gloves.	Closing the door or curtains provides privacy. Proper bed height helps reduce back strain while performing the procedure. The side-lying position with head forward prevents aspiration of fluid into lungs. Towel and emesis basin protect the patient from dampness. Suction provides means to remove oral hygiene products and saliva from oral cavity. Gloves prevent the spread of microorganisms.
5. Gently open the patient's mouth by applying pressure to the lower jaw at the front of the mouth. Do not use fingers to hold the patient's mouth open. Use another toothbrush or mouth prop (Figure 1) to keep the mouth open. Remove dentures, if present.	Patients with altered cognition may inadvertently bite fingers inserted into the mouth. Removal of dentures allows for cleaning of dentures and oral cavity.

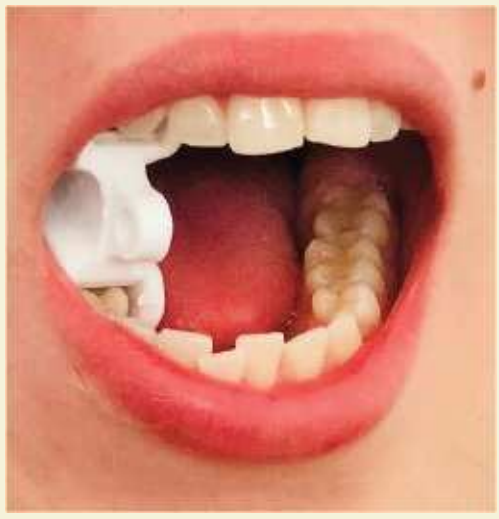


FIGURE 1. Example of a mouth prop. (*Source:* Used with permission from Neo-Health Services, Inc. © 2011 OrofacialMyology.com. All rights reserved.)

6. If using a regular toothbrush and suction catheter, one care giver provides oral cleaning and the other removes secretions with the suction catheter.	This allows for efficient care to reduce the risk of aspiration.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

7. Brush the teeth and gums carefully with toothbrush and paste or other oral cleanser (Figure 2). Lightly brush the tongue.	The toothbrush provides friction necessary to clean areas where plaque and tartar accumulate.

FIGURE 2. Carefully brushing patient's teeth.

8. Moisten toothbrush with water to rinse the oral cavity. **Position the patient's head to allow for return of water. If using regular toothbrush, use suction catheter to remove the water and cleanser from oral cavity (Figure 3).**	Rinsing helps clean debris from the mouth. Suction toothbrush removes fluids and cleansers.

FIGURE 3. Using suction to remove excess fluid.

9. Brush the tongue gently with toothbrush or tongue scraper (MFMER, 2019a).	This removes coating on the tongue. Gentle motion does not stimulate the gag reflex.
10. Using the suction swab, apply a therapeutic antiseptic mouth rinse as indicated. Apply oral moisturizer as indicated.	Therapeutic and antiseptic mouth rinses reduce bacteria and reduce plaque, gingivitis, tartar, and reduce the incidence of health care–associated pneumonia (AACN, 2017; ADA, 2019; Chick & Wynne, 2020). Oral moisturizers provide moisture to the mucosa.
11. Clean the dentures before replacing.	Cleaning maintains dentures and oral hygiene. Plaque can accumulate on dentures and promote oropharyngeal colonization of pathogens.
12. Apply lubricant to the patient's lips.	This prevents drying and cracking of lips.
13. Remove equipment and return the patient to a position of comfort. Remove gloves. Perform hand hygiene. Raise the side rail and lower the bed.	Promotes patient comfort and safety. Removing gloves properly reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
	Proper removal of PPE reduces the risk for infection transmission and

14. Remove additional PPE, if used. Perform hand hygiene.

contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Record oral assessment, significant observations, and unusual findings, such as bleeding or inflammation. Document any teaching done. Document care provided and patient response.

Sample Documentation

7/10/25 0945 Oral care performed. Oral cavity mucosa pink and moist. Small amount of bleeding noted from gums after using soft-bristled toothbrush. Resolved spontaneously when brushing completed. No evidence of ulceration. Lips slightly dry; lip moisturizer applied.

—C. Stone, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient begins to bite the toothbrush:* Do not jerk the toothbrush out. Wait for the patient to relax mouth before removing the toothbrush and continuing with care. Use distraction, gentle touch, or massage to divert the patient.
- *Mouth is extremely dry with crusts that remain after oral care provided:* Increase frequency of oral hygiene. Apply mouth moisturizer to oral mucosa. Monitor fluid intake and output to ensure adequate intake of fluid.

SPECIAL CONSIDERATIONS

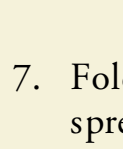
- Suction toothbrushes may be used with patients with dysphagia (figure 4).
- Use a soft bristled toothbrush with a small head even when the patient has no or few teeth. It is the only effective way to remove plaque and debris from the teeth, gums, and tongue.
- Automatic toothbrushes, electric or battery operated, are simple to use and can be used to removing debris and plaque and clean the teeth effectively. Use of an electric toothbrush provides superior oral hygiene care when oral hygiene is provided by a caregiver (Vannah & Sammarco, 2019).
- The use of chlorhexidine gluconate (CHG) as part of oral hygiene has been integrated into oral hygiene regimens and is available as an oral rinse, oral spray, and dental gel (AACN, 2017; de Camargo et al., 2019). The use of CHG as part of protocols for systematic oral care for critically ill patients has been shown to reduce risk of ventilator-associated pneumonia (VAP) (AACN, 2017; Chen et al., 2015).

FIGURE 4. Example of a suction toothbrush. (*Source:* Permission granted by Sage Products LLC.)

Skill 32-4 Making an Unoccupied Bed

DELEGATION CONSIDERATIONS

The making of an unoccupied bed may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.



EQUIPMENT

- One large flat sheet

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- One fitted sheet
- Lifting/repositioning sheet or friction-reducing sheet (optional)
- Blankets
- Bedspread
- Pillowcases
- Linen hamper or bag
- Bedside chair
- Waterproof protective pad (optional)
- Disposable gloves
- Additional PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
 1. Perform hand hygiene. Put on PPE, as indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
2. Explain to the patient what you are going to do and the reason for doing it, if the patient is present in the room.	Explanation facilitates engagement in care.
3. Assemble necessary equipment on the bedside stand, overbed table, or other surface within reach.	Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
4. Adjust the bed to a comfortable working height (VHACEOSH, 2016). Drop the side rails.	Having the bed at the proper height prevents back and muscle strain. Having the side rails down reduces strain on the nurse while working.
5. Disconnect the call bell or any tubes from bed linens.	Disconnecting devices prevents damage to the devices.
6. Put on gloves. Loosen all linen as you move around the bed, from the head of the bed on the far side to the head of the bed on the near side.	Gloves prevent the spread of microorganisms. Loosening the linen helps prevent tugging and tearing on linen. Loosening the linen and moving around the bed systematically reduce strain caused by reaching across the bed.
7. Fold reusable linens, such as sheets, blankets, or spread, in place on the bed in fourths and hang them over a clean chair.	Folding saves time and energy when reusable linen is replaced on the bed. Folding linens while they are on the bed reduces strain on the nurse's arms. Some facilities change linens only when soiled.
8. Snugly roll all the soiled linen inside the bottom sheet. Hold linen away from your body and place directly into the laundry hamper (Figure 1). **Do not place on floor or furniture. Do not hold soiled linens against your clothing.**	Rolling soiled linens snugly and placing them directly into the hamper helps prevent the spread of microorganisms. The floor is heavily contaminated; soiled linen will further contaminate furniture. Soiled linen contaminates the nurse's clothing, and this may spread organisms to another patient.
9. If possible, shift the mattress up to the head of the bed. If the mattress is soiled, clean and dry according to facility policy before applying new sheets.	This allows more foot room for the patient.
 10. Remove your gloves, unless indicated for transmission-based precautions. Perform hand hygiene. Place the bottom sheet on the mattress and secure the bottom sheet over the corners at the head and foot of the mattress.	Gloves are not necessary to handle clean linen. Hand hygiene prevents the spread of microorganisms. Secures bottom sheet on one side of the bed.

11. Push the sheet open to the center of the mattress, pulling the sheet taut from the secured corners (Figure 2).	Making the bed on one side and then completing the bedmaking on the other side saves time. Pulling the sheet taut keeps it in place on the mattress. Having bottom linens free of wrinkles reduces patient discomfort.

FIGURE 1. Bundling soiled linens in bottom sheet and holding them away from clothing.

FIGURE 2. Pushing the bottom sheet open to the center of the mattress.

12. If using, place the lifting/repositioning or friction-reducing sheet with its center fold in the center of the bed and positioned so it will be located under the patient's midsection; open it and fanfold to the center of the mattress (Figure 3). If a protective pad is used, place it over the lifting/repositioning or friction-reducing sheet in the proper area and open to the center fold. Not all facilities use lifting/repositioning sheets routinely. The nurse may decide to use one or a friction-reducing sheet based on patient circumstances. In some institutions, the protective pad doubles as a lifting/repositioning sheet. Tuck the lifting/repositioning or friction-reducing sheet securely under the mattress.	If the patient soils the bed, lifting/repositioning or friction-reducing sheet and pad can be changed without changing the bottom and top linens. Having all bottom linens in place before tucking them under the mattress avoids unnecessary moving about the bed. A lifting/repositioning or friction-reducing sheet can aid moving the patient in bed.
13. Move to the other side of the bed to secure bottom linens. Pull the bottom sheet tightly and secure over the corners at the head and foot of the mattress. Pull the lifting/repositioning or friction-reducing sheet tightly and tuck it securely under the mattress.	This removes wrinkles from the bottom linens, which can cause patient discomfort and promote skin breakdown.
14. Place the top sheet on the bed with its center fold in the center of the bed and with the hem even with the head of the mattress. Unfold the top sheet. Follow same procedure with top blanket or spread, placing the upper edge about 6 inches below the top of the sheet.	Opening linens by shaking them spreads organisms into the air. Holding linens overhead to open causes strain on the nurse's arms.
15. Tuck the top sheet and blanket under the foot of the bed on the near side. Miter the corners (Figure 4).	This saves time and energy and keeps the top linen in place.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 3. Placing lifting/repositioning sheet on bed.

FIGURE 4. Mitering corner of top sheet and blanket.

16. Fold the upper 6 inches of the top sheet down over the spread and make a cuff.
    This makes it easier for the patient to get into bed and pull up the covers.

17. Move to the other side of the bed and follow the same procedure for securing top sheets under the foot of the bed and making a cuff (Figure 5).
    Working on one side of the bed at a time saves energy and is more efficient.

FIGURE 5. Cuffing top linens.

18. Place the pillows on the bed. Open each pillowcase in the same manner as you opened other linens. Gather the pillowcase over one hand toward the closed end. Grasp the pillow with the hand inside the pillowcase. Keep a firm hold on the top of the pillow and pull the cover onto the pillow. Place the pillow at the head of the bed.
    Opening linens by shaking causes organisms to be carried on air currents. Covering the pillow while it rests on the bed reduces strain on the nurse's arms and back.

19. Fan-fold or pie-fold the top linens.
    Having linens opened makes it more convenient for the patient to get into bed.

20. Secure the signal device on the bed, according to facility policy.
    The patient will be able to call for assistance as necessary. Promotes patient comfort and safety.

21. Raise the side rail and lower the bed.
    This promotes patient comfort and safety.

22. Dispose of soiled linen according to facility policy.
    This deters the spread of microorganisms.

23. Remove any other PPE, if used. Perform hand hygiene.
    Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Changing of bed linens does not require documentation. The use of a specialty bed or bed equipment should be documented.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Lifting/repositioning sheet is not available:* A flat sheet can be folded in half to substitute for a lifting/repositioning sheet, but extra care must be taken to avoid wrinkles in the bed.
- *Patient is frequently incontinent of stool or urine:* More than one protective pad can be placed under the patient to protect the bed, but take care to ensure that the patient is not lying on wrinkles from linens.

SPECIAL CONSIDERATIONS

- Many different types of specialty beds are available for use as part of treatment and prevention of many health issues, such as treatment of pressure injuries. Refer to the manufacturer's recommendations and instructions on use of specialty linens and products with these types of equipment.

Skill 32-5 Making an Occupied Bed

DELEGATION CONSIDERATIONS

The making of an occupied bed may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- One large flat sheet
- One fitted sheet
- Lifting/repositioning sheet (optional) or friction-reducing sheet
- Blankets
- Bedspread
- Pillowcases
- Linen hamper or bag
- Bedside chair
- Protective pad (optional)
- Disposable gloves
- Additional PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Check the health care record for limitations on the patient's physical activity.	This facilitates patient engagement in care, determines level of activity, and promotes patient safety.
 2. Perform hand hygiene. Put on PPE, as indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient. Explain what you are going to do.	Patient identification validates the correct patient and correct procedure. Discussion and explanation allay anxiety and prepare the patient for what to expect.
4. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

5. Close the curtains around the bed and close the door to the room, if possible.	This ensures the patient's privacy.
6. Adjust the bed to a comfortable working height (VHACEOSH, 2016).	Having the bed at the proper height prevents back and muscle strain.
7. Lower the side rail nearest you, leaving the opposite side rail up. Place the bed in a flat position unless contraindicated.	Having the mattress flat makes it easier to prepare a wrinkle-free bed.
8. Put on gloves. Check bed linens for the patient's personal items. **Disconnect the call bell or any tubes/drains from bed linens.**	Gloves prevent the spread of microorganisms. It is costly and inconvenient when personal items are lost. Disconnecting tubes from linens prevents discomfort and accidental dislodging of the tubes.
9. Place a bath blanket over the patient. Have the patient hold on to the bath blanket while you reach under it and remove the top linen (Figure 1). Leave the top sheet in place if a bath blanket is not used and loosen from bottom of bed. Fold linen that is to be reused over the back of a chair. Discard soiled linen in a laundry bag or hamper. **Do not place on floor or furniture. Do not hold soiled linens against your clothing.**	The blanket provides warmth and privacy. Placing linens directly into the hamper helps prevent the spread of microorganisms. The floor is heavily contaminated; soiled linen will further contaminate furniture. Soiled linen contaminates the nurse's clothing, and this may spread organisms to another patient.

FIGURE 1. Removing top linens from under bath blanket.

10. If possible, and another person is available to assist, grasp the mattress securely and shift it up to head of bed.	This allows more foot room for the patient.
11. Assist the patient to turn toward the opposite side of the bed, and reposition the pillow under the patient's head. If the patient is partially able or unable to assist, friction-reducing devices, lifting/repositioning sheets, lateral transfer devices, and a full-body sling are potential equipment to consider, based on screening and assessment. Consider available bed features (turning, pressure release, rotation) to assist with the action (VA Mobile Health, n.d.).	This allows the bed to be made on the vacant side. Use of safe patient handling and mobility devices is best practice to prevent patient and health care provider injury (VA Mobile Health, n.d.; VHACEOSH, 2016).
12. Loosen all bottom linens from the head, foot, and side of the bed.	This facilitates removal of linens.
13. Fan-fold or roll soiled linens as close to the patient as possible (Figure 2).	This makes it easier to remove linens when the patient turns to the other side.
14. Use clean linen and make the near side of the bed. Place the bottom sheet in the center of the bed. Open the sheet and pull the bottom sheet over the corners at the head and foot of the mattress (Figure 3). Push	Opening linens on the bed reduces strain on the nurse's arms and diminishes the spread of microorganisms. Centering the sheet ensures sufficient coverage for both sides of the mattress. Positioning under the old

the sheet toward the center of the bed, pulling it taut and positioning it under the old linens (Figure 4).	linens makes it easier to remove linens.
15. If using, place the lifting/repositioning or friction-reducing sheet with its center fold in the center of the bed and positioned so it will be located under the patient's midsection. Open the lifting/repositioning or friction-reducing sheet and fan-fold it to the center of the mattress. Tuck it securely under the mattress (Figure 5). If a protective pad is used, place it over the lifting/repositioning or friction-reducing sheet in the proper area and open to the center fold. Not all facilities use lifting/repositioning sheets routinely. The nurse may decide to use one.	If the patient soils the bed, lifting/repositioning or friction-reducing sheet and pad can be changed without the bottom and top linens on the bed. A lifting/repositioning or friction-reducing sheet can aid in moving the patient in bed.

FIGURE 2. Moving soiled linen as close to patient as possible.

FIGURE 3. Pulling the bottom sheet over the corners at the head and foot of the mattress.

FIGURE 4. Pushing the bottom sheet toward the center of the bed, positioning it under old linens.

FIGURE 5. Tucking lifting/repositioning or friction-reducing sheet tightly.

16. Raise the side rail. Assist the patient to roll over the folded linen in the middle of the bed toward you. If the patient is partially able or unable to assist, friction-reducing devices, lifting/repositioning sheets, lateral transfer devices, and a full-body sling are potential equipment to consider, based on screening and assessment. Consider available bed features (turning, pressure release, rotation) to assist with the action (VA Mobile Health, n.d.). Reposition pillow and bath blanket or top sheet. Move to other side of the bed and lower the side rail.	This ensures patient safety. The movement allows the bed to be made on the other side. Use of safe patient handling and mobility devices is best practice to prevent patient and health care provider injury (VA Mobile Health, n.d.; VHACEOSH, 2016). The bath blanket provides warmth and privacy.
17. Loosen and remove all bottom linen (Figure 6). Discard soiled linen in laundry bag or hamper. **Do not place on floor or furniture. Do not hold soiled linens against your clothing.**	Placing linens directly into the hamper helps prevent the spread of microorganisms. The floor is heavily contaminated; soiled linen will further contaminate the furniture. Soiled linen contaminates the nurse's clothing, and this may spread organisms to another patient.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

18. Ease clean linen from under the patient. Pull the bottom sheet taut and secure at the corners at the head and foot of the mattress. Pull the lifting/repositioning or friction-reducing sheet tight and smooth. Tuck it securely under the mattress.	This removes wrinkles and creases in the linens, which are uncomfortable to lie on.
19. Assist the patient to turn back to the center of bed. If the patient is partially able or unable to assist, friction-reducing devices, lifting/repositioning sheets, lateral transfer devices, and a full-body sling are potential equipment to consider, based on screening and assessment. Consider available bed features (turning, pressure release, rotation) to assist with the action (VA Mobile Health, n.d.). Remove the pillow and change the pillowcase. Open each pillowcase in the same manner as you opened other linens. Gather the pillowcase over one hand toward the closed end. Grasp the pillow with the hand inside the pillowcase. Keep a firm hold on the top of the pillow and pull the cover onto the pillow. Place the pillow under the patient's head.	Use of safe patient handling and mobility devices is best practice to prevent patient and health care provider injury (VA Mobile Health, n.d.; VHACEOSH, 2016). Opening linens by shaking causes organisms to be carried on air currents.
20. Apply top linen, sheet, and blanket, if desired, so that it is centered. Fold the top linens over at the patient's shoulders to make a cuff. Have the patient hold on to top linen and remove the bath blanket from underneath (Figure 7). Discard soiled linen in laundry bag or hamper. **Do not place on floor or furniture. Do not hold soiled linens against your clothing.** Remove gloves. Perform hand hygiene.	This allows bottom hems to be tucked securely under the mattress and provides for privacy. Placing linens directly into the hamper helps prevent the spread of microorganisms. The floor is heavily contaminated; soiled linen will further contaminate the furniture. Soiled linen contaminates the nurse's clothing, and this may spread organisms to another patient. Removing gloves properly reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

FIGURE 6. Removing soiled bottom linens from other side of bed.

FIGURE 7. Removing bath blanket from under top linens.

21. Secure top linens under foot of mattress and miter corners. Loosen top linens over the patient's feet by grasping them in the area of the feet and pulling gently toward the foot of bed.	This provides for a neat appearance. Loosening linens over the patient's feet gives more room for movement.
22. Return the patient to a position of comfort. Raise the side rail and lower the bed. Reattach call bell.	This promotes patient comfort and safety.
23. Dispose of soiled linens according to facility policy.	This deters the spread of microorganisms.
24. Remove any other PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Changing of bed linens does not require documentation. The use of a specialty bed or bed equipment should be documented. Document any significant observations and communication.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Dirty linens are grossly contaminated with urinary or fecal drainage:* Obtain an extra towel or protective pad. Place the pad under and over the soiled linens so that new linens will not be in contact with soiled linens. Clean and dry the mattress according to facility policy before applying new sheets.

SPECIAL CONSIDERATIONS

Older Adult Considerations

- Using a soft bath blanket or a flannelette blanket as a bottom sheet may solve the problem of "coldness" for older adult patients with vascular problems or arthritis.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Work through the Nursing Care Plan for Kylie Simpson and University Students on pages 1118–1120 to help develop your clinical reasoning and clinical judgment skills.
. Practice the art of back massage with a willing partner until you feel comfortable and confident including this nursing measure in your routine care. Discuss with other students the therapeutic benefits of massage, and identify nursing situations for which it may be the primary therapy.
. Interview people of different ages and cultural backgrounds about their hygiene practices. Ask specific questions about the type of nursing assistance they would require if hospitalized and unable to meet their hygiene needs independently. Are there special products or equipment they would need? To what extent are nurses obliged to respect the hygiene preferences of patients?

PRACTICING FOR NCLEX

. A nurse is scheduling hygiene for patients on the unit. What is the priority the nurse uses to guide planning for patient's personal hygiene?

a. When the patient had their most recent bath
b. The patient's usual hygiene practices and preferences
c. Where the bathing fits in the nurse's schedule
d. The time that is convenient for the AP

. A nurse caring for patients in a critical care unit knows that providing good oral hygiene is an essential to good patient outcomes, especially for those receiving mechanical ventilation. What are positive outcomes expected from this care? Select all that apply.

a. Promoting the patient's sense of well-being
b. Preventing deterioration of the oral cavity
c. Contributing to decreased incidence of aspiration pneumonia
d. Eliminating the need for flossing
e. Decreasing oropharyngeal secretions
f. Compensating for an inadequate diet

. A nurse assisting a patient with a bed bath observes the older adult has dry skin, which the patient states is "itchy." Which intervention is appropriate?

a. Bathe the patient more frequently.
b. Use an emollient on the dry skin.
c. Explain that this is expected as people age.
d. Limit the patient's fluid intake.

. A charge nurse in a skilled nursing facility is working to reduce patients' foot and nail problems. The charge nurse reminds the nurses and APs to closely observe which of these patients at higher risk? Select all that apply.

a. Patient taking antibiotics for chronic bronchitis
b. Patient with type 2 diabetes

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

c. Patient who has obesity
d. Patient who frequently bites their nails
e. Patient with prostate cancer
f. Patient who frequently washes their hands

. When assessing the skin, nurses use techniques to provide complete data and correct documentation. Which actions are appropriate during the skin assessment? Select all that apply.

a. Comparing bilateral parts for symmetry
b. Proceeding in a toe-to-head, systematic manner
c. Using standard terminology to communicate and document findings
d. Avoiding using data from the nursing history to direct the assessment
e. Documenting only skin abnormalities on the health record
f. When risk factors are identified, following up with a related skin assessment

. A nurse is caring for an adolescent with severe acne. Which recommendations would be most appropriate to include in the teaching plan for this patient? Select all that apply.

a. Wash the skin twice a day with a mild cleanser and warm water.
b. Use cosmetics liberally to cover blackheads.
c. Apply emollients on the area.
d. Squeeze blackheads as they appear.
e. Keep hair off the face and wash hair daily.
f. Avoid tanning booth exposure and use sunscreen.

. A nurse is performing oral care on a patient who has advanced dementia. The nurse notes that the mouth is extremely dry with crusts remaining after the oral care. What action will the nurse take next?

a. Recommend a consultation with an oral surgeon.
b. Communicate the condition to the health care team.
c. Gently scrape the oral cavity with a tongue depressor.
d. Increase the frequency of the oral hygiene and apply mouth moisturizer to oral mucosa.

. A nursing student asks an experienced nurse why they provide massage for their patients. Which of these would be reflected in the nurse's response?

a. To help with pain management
b. To provide comfort
c. To communicate to patients through touch
d. To energize patients, especially those with dementia
e. To facilitate healing after back or spinal surgery
f. To help increase circulation

. A nurse is caring for a patient with an eye infection with a moderate amount of discharge. What is the most appropriate technique for the nurse to use when cleansing this patient's eyes?

a. Using diluted hydrogen peroxide on a clean washcloth to wipe the eyes
b. Wiping the eye from the outer canthus toward the inner canthus
c. Positioning the patient on the opposite side of the eye to be cleansed
d. Cleansing the eye using a different section of the cloth for each stroke until clean

. A nurse in a long-term care facility observes the AP providing foot care for patients. Which actions by the AP require the nurse to intervene? Select all that apply.

a. Bathing the feet thoroughly in a mild soap and tepid water solution
b. Soaking the resident's feet in warm water and bath oil
c. Drying the feet and area between the toes thoroughly
d. Applying an alcohol rub for odor and dryness to the feet
e. Applying an antifungal foot powder
f. Cutting the toenails at the lateral corners when trimming the nail

. A nurse in a memory care unit is assisting a patient with dementia with bathing. Which nursing action will enhance patient comfort and prevent anxiety?

a. Shifting the focus of the interaction to the "process of bathing"
b. Washing the face and hair at the beginning of the bath
c. Using music to soothe anxiety and agitation

d. Avoiding towel baths or forms of bathing with which the patient is unfamiliar

. A nurse is teaching a nursing student how to perform perineal care for patients. What actions are appropriate when performing this procedure? Select all that apply.

a. For male and female patients, wash the groin area with a small amount of soap and water and rinse.
b. For a female patient, spread the labia and move the washcloth from the anal area toward the pubic area.
c. For male and female patients, always proceed from the most contaminated area to the least contaminated area.
d. For male and female patients, use a clean portion of the washcloth for each stroke.
e. For a male patient, clean the tip of the penis first, moving the washcloth in a circular motion from the meatus outward.
f. In an uncircumcised male patient, avoid retracting the foreskin (prepuce) while washing the penis.

. A home care nurse is assisting an older adult with an unsteady gait with a tub bath. Which action is recommended in this procedure?

a. Adding bath oil to the water to prevent dry skin
b. Allowing the patient to lock the door to guarantee privacy
c. Assisting the patient in and out of the tub to prevent falling
d. Keeping the water temperature very warm because older adults chill easily

. A nurse is about to bathe a female patient who has an IV in the forearm. The patient's gown, which does not have snaps on the sleeves, needs to be removed prior to bathing. How will the nurse proceed?

a. Quickly disconnecting the IV tubing closest to the patient and thread it through the gown sleeve
b. Cutting the gown with scissors to allow arm movement
c. Threading the bag and tubing through the gown sleeve, keeping the line intact
d. Temporarily disconnecting the tubing from the IV container, threading it through the gown

. A nurse is caring for a 25-year-old patient who is unresponsive following a head injury. The patient has several piercings in the ears and nose that appear crusted and slightly inflamed. What is the most appropriate action to care for this patient's piercings?

a. Avoiding removing or washing the piercings until the patient is responsive
b. Rinsing the sites with warm water and remove crusts with a cotton swab
c. Washing the sites with alcohol and apply an antibiotic ointment
d. Removing the jewelry and allow the sites to heal over

. An RN in a long-term care facility supervises APs as they provide hygiene to older adults. What action by the AP will the nurse correct?

a. When providing perineal care, washing the area from front to back
b. Insisting the older adult must take a bath or shower each day
c. Telling the patient to avoid soaking feet, helps the patient dry between the toes
d. Covering areas not being bathed with a bath blanket

ANSWERS WITH RATIONALES

. **b.** The patient's preferences, practices, and rituals should always be taken into consideration, unless there is a clear threat to health. The patient and nurse should work together to come to a mutually agreeable time and method to accomplish the patient's personal hygiene. The availability of staff to assist may be important, but the patient's preferences are a higher priority.

. **a, b, c.** Adequate oral hygiene is essential for promoting the patient's sense of well-being and preventing deterioration of the oral cavity. Diligent oral hygiene and use of chlorhexidine gluconate (CHG) in critical care areas, can limit the growth of pathogens in oropharyngeal secretions, decreasing the incidence of ventilator-associated pneumonia, aspiration pneumonia, and other systemic diseases. Oral care does not eliminate the need for flossing, decrease oropharyngeal secretions, or compensate for poor nutrition.

. **b.** An emollient soothes dry skin, whereas frequent bathing increases dryness. Telling the patient this is normal with aging and does not help resolve the issue. Limiting fluid intake can promote dehydration and exacerbate dry skin.

. **b, c, d, f.** Variables known to cause nail and foot problems include deficient self-care abilities, vascular disease, arthritis, diabetes mellitus, history of biting nails or trimming them improperly, frequent or prolonged exposure to chemicals or water, trauma, ill-fitting shoes, and obesity. Antibiotic use and prostate cancer do not predispose to foot or nail problems.

. **a, b, c, f.** During skin assessment, the nurse should compare bilateral parts for symmetry, use standard terminology to communicate and document findings, and perform the appropriate skin assessment when risk factors are identified. The nurse should proceed in a head-to-toe systematic manner, using cues/data from the nursing history to direct the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

assessment. When documenting a physical assessment of the skin, the nurse should describe exactly what is observed or palpated, including appearance, texture, size, location or distribution, and characteristics of any findings.

. **a, e, f.** Washing the skin removes oil and debris, hair should be kept off the face and washed daily to keep oil from the hair off the face. Exposure to UV light should be avoided, especially when using acne treatments. Liberal use of cosmetics and emollients can clog the pores, worsening acne. Squeezing blackheads is discouraged because it may lead to infection.

. **d.** If initial oral care results in continued dryness of the oral cavity with crusting, the nurse should increase frequency of oral hygiene, apply mouth moisturizer to oral mucosa, and monitor fluid intake and output to ensure adequate intake of fluid. It is not necessary to report this condition prior to providing the interventions mentioned above; however, mouth care and re-evaluation of the oral cavity is documented. The crusts should not be scraped with a tongue depressor.

. **a, b, c, f.** The benefits of massage include general relaxation and increased circulation, pain relief, sleep promotion, and increased patient comfort and well-being. Massage also provides an opportunity for the nurse to communicate and connect with the patient through touch. Back massage is contraindicated if the patient has had back surgery or has fractured ribs.

. **d.** The nurse applies gloves for the cleaning procedure, uses water or normal saline, and a clean washcloth or gauze to cleanse the eyes. After dampening a cleaning cloth with the solution of choice, the nurse wipes once while moving from the inner canthus to the outer canthus of the eye to reduce forcing debris into the area drained by the nasolacrimal duct. The nurse should turn the cleansing cloth and use a different section for each stroke until the eye is clean.

. **b, d, f.** The nurse corrects the AP for soaking the feet or using alcohol and reminds them to use moisturizer if the feet are dry. Digging into or cutting the toenails at the lateral corners when trimming the nails requires correction; toenails should be trimmed straight across. Guidelines for foot care include bathing the feet thoroughly in a mild soap and tepid water solution; drying feet thoroughly, including the area between the toes; and applying an antifungal foot powder when requested.

. **c.** The nurse use music to soothe anxiety and agitation. The nurse should also shift the focus of the interaction from the "task of bathing" to the needs and abilities of the patient, and focus on comfort, safety, autonomy, and self-esteem, in addition to cleanliness. Wash the face and hair at the end of the bath or at a separate time. Water dripping in the face and having a wet head are often the most upsetting parts of the bathing process for people with dementia. The nurse should also consider methods for bathing aside from showers and tub baths. Towel baths, washing under clothes, and bathing "body sections" one day at a time, as well as dry shampoo or "shower cap" shampoos, are additional options.

. **a, d, e.** Wash and rinse the groin area (both male and female patients) with a small amount of soap and water, and rinse. For male and female patients, always proceed from the least contaminated area to the most contaminated area and use a clean portion of the washcloth for each stroke. For a male patient, clean the tip of the penis first, moving the washcloth in a circular motion from the meatus outward. For a female patient, spread the labia and move the washcloth from the pubic area toward the anal area. In an uncircumcised male patient (teenage or older), retract the foreskin (prepuce) while washing the penis and return it to its original position when finished.

. **c.** Safe nursing practice requires that the nurse assists a patient with an unsteady gait in and out of the tub. Adding bath oil to the bath water poses a safety risk because it makes the patient and tub slippery. Although privacy is important, if the patient locks the door, the nurse cannot help if there is an emergency. The water should be comfortably warm at 43° to 46°C. Older adults have an increased susceptibility to burns due to diminished sensitivity.

. **c.** Threading the bag and tubing through the gown sleeve maintains a closed system and prevents contamination. No matter how quickly performed, any disconnection of IV tubing results in a breach of the sterile system, creating risk for infection. Cutting a gown is not an alternative except in an emergency.

. **b.** When providing care for piercings, the nurse performs hand hygiene, applies gloves, then cleanses the site of all crusts and debris by rinsing the site with warm water and removing the crusts with a cotton swab. The nurse should then apply a dab of liquid-medicated cleanser, per policy, to the area, turn the jewelry back and forth to work the cleanser around the opening, rinse well, remove gloves, and perform hand hygiene. The nurse should not use alcohol, peroxide, or ointments at the site and should avoid removing piercings unless it is absolutely necessary (e.g., when an MRI is ordered.)

. **b.** Older adults tend to develop dry skin; bathing frequency will change accordingly. Soaking adults' feet is not recommended. It is appropriate to keep a patient warm with bath blankets and provide perineal care washing from front to back.

Skin Integrity and Wound Care

Mary Biesicker

Mary, who is 84 years old, has been cared for at home by her daughter since being hospitalized last year for a cerebrovascular accident (stroke). She has been unable to take care of herself, finds it increasingly more difficult to get out of bed, and is having more frequent episodes of incontinence. According to her daughter, Mary has developed a “blister” on her back. Mary is being assessed by the home health care nurse at the request of her daughter, who is finding it difficult to care for her mother alone.

Lucius Everly

Lucius, a 52-year-old who has a history of diabetes and circulatory problems, underwent abdominal surgery several days ago and is in the critical care unit. He is slouched down in bed, his abdominal dressing is moist, and only part of the tape securing the dressing is adhering to the skin. His level of consciousness is decreased, and he responds only to moderate touch and pain. Further assessment reveals the beginning of a pressure injury on his heel.

Sam Bentz

Sam, a 56-year-old, has been admitted to the hospital for aggressive treatment of a bone infection that has not responded to usual treatment methods. Sam is 5 ft 4 inches tall and weighs more than 300 lb. They tell you, “Last time I was here, my skin got really irritated and I developed several skin wounds.”

Lippincott DocuCare Additional patient scenarios available in ***Lippincott DocuCare***.

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Discuss the processes involved in wound healing.
. Identify factors that affect wound healing.
. Identify patients at risk for pressure injury development.
. Describe the method of staging of pressure injuries.
. Accurately assess and document the condition of wounds.
. Provide nursing interventions to prevent pressure injuries.
. Implement appropriate dressing changes for different kinds of wounds.
. Provide information to patients and caregivers for self-care of wounds at home.
. Apply hot and cold therapy effectively and safely.

The skin is the body's first line of defense, protecting the underlying structures from invasion by organisms. Maintaining an intact skin surface is important because a break or disruption in this integrity is potentially dangerous and possibly life threatening. The nurse plays a major role in maintaining the patient's skin integrity, identifying risk factors that predispose a patient to a break in integrity, intervening to prevent or reduce a patient's risk for impaired skin integrity, and providing specific wound care when breaks in integrity arise. Additional information related to general skin care is discussed in Chapter 32.

Development and maintenance of the knowledge and skills necessary to implement evidence-based wound care is an essential component of nursing care. Using the nursing process, an individualized care plan is developed to assess the patient and the wound; identify and prevent complications; implement and evaluate skills essential to wound care; and provide physical and emotional support to facilitate healing, adaptation, and self-care. Wound care may be required in any health care setting and complex wound care at home is on the rise.

This chapter provides information about disruptions in skin and tissue integrity, including wounds and pressure injuries. Because applications of heat and cold are used to treat altered skin integrity, a discussion of those treatment modalities is also included. Refer to the Reflective Practice display for an illustration of nursing care issues related to skin integrity.

ANATOMY AND PHYSIOLOGY OF THE INTEGUMENTARY SYSTEM

Knowledge of the basic anatomy and physiology of the integumentary system and understanding the role of this system in the body provides a foundation for assessment. This knowledge also informs the analysis of data and provides rationale for planning and implementing interventions that promote and restore optimal skin integrity.

Structures of the Skin

The skin, or integument, is the largest organ of the body and has multiple functions. The skin covers the entire body and is continuous with mucous membranes at normal body orifices. It is essential for maintaining life.

The integumentary system is made up of the skin, the subcutaneous layer directly under the skin, and the appendages of the skin, including glands in the skin, hair, and nails. The integumentary system also includes the blood vessels, nerves, and sensory organs of the skin.

The skin has three layers: the epidermis, the dermis, and the subcutaneous tissue layer (Jensen, 2019; Norris, 2019). A cross-section of normal skin is illustrated in Figure 33-1 on page 1151.

The top layer, or outermost portion, is the **epidermis**. The epidermis is composed of layers of stratified epithelial cells. These cells fuse to form a protective, waterproof layer of keratin material. Epithelial cells have no blood vessels of their own and depend on underlying tissues for nourishment and waste removal. When well nourished, epithelium regenerates relatively easily and quickly.

The second layer of skin, the **dermis**, consists of a framework of elastic connective tissue comprised primarily of collagen. Nerves, hair follicles, glands, immune cells, and blood vessels are located in this layer (Norris, 2019). Each hair consists of the shaft, which projects through the dermis beyond the surface of the skin, and the hair follicle, which lies in the dermis.

The dermis rests on the **subcutaneous tissue**, the bottom layer that anchors the skin layers to the underlying tissues of the body. The subcutaneous tissue consists of adipose tissue, made up of lobules of fat cells, and connective tissue. This layer stores fat for energy, serves as a heat insulator for the body, and provides a cushioning effect for protection.

This fatty tissue layer contains blood and lymph vessels, nerves, and fat cells.

Functions of the Skin and Mucous Membranes

The skin has multiple functions: protection, temperature regulation, psychosocial, sensation, vitamin D production, immunologic, absorption, and elimination. See Table 33-1 (on page 1152) for details of each of these functions.

Mucous membranes line body cavities that open to the outside of the body, joining with the skin. They can also be found in the digestive tract, the respiratory passages, and the urinary and reproductive tracts. Epithelium covers the mucous membrane surfaces and contains cells that secrete mucus. Mucous membranes have receptors that offer the body protection. For example, an irritating substance in the upper respiratory tract causes a person to sneeze, and food caught in the larynx or trachea causes a person to cough. Sneezing and coughing are protective mechanisms that help rid the body of foreign materials. Mucous membranes are insensitive to temperature, except in the mouth and rectum, but are sensitive to pressure. Mucous membranes also function to absorb substances from their surface. For example, digested food is absorbed through the mucous membrane in the small intestine.

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO ETHICAL AND LEGAL SKILLS

I had a tough clinical 2 weeks ago while caring for Lucius Everly, a critical care postop patient with a history of diabetes and circulation problems. The nurse I was working with had floated to the unit on this day, but I didn't know that at the time. Mr. Everly appeared to be neglected by other caregivers; because he was not communicating and had a decreased level of consciousness, he could not express his needs. In my opinion, he needed bathing, wound care, repositioning in bed, and some additional attention I was unable to provide independently. Although the nurse did their best to educate me on the history and status of the patient, the nurse spoke about Mr. Everly over the bed as if he wasn't even there. In my opinion, the nurse did not respect his inability to communicate. I became frustrated because she did not seem to share my sense of concern for him. The nurse was noncommittal when I asked specifically about foot care and what I could do to promote circulation in his feet. My frustration increased when I realized that he was developing a pressure ulcer on his heel.

Thinking Outside the Box: Possible Courses of Action

- Tell my clinical instructor of my frustrations earlier in the day so my patient's care could have been addressed earlier and my frustrations wouldn't have compounded.
- Go to the nurse and tell them that I wasn't comfortable with the care they were providing, insisting that more needed to be done for this patient.
- Ask the charge nurse to assess the quality of care that my patient was receiving compared to what he needed.

Evaluating a Good Outcome: How Do I Define Success?

- Patient receives a higher quality of care designed to maintain his dignity.
- The nurse responds positively to the constructive feedback, making changes to the care that is being provided to the patient.
- By addressing the problem earlier in the process, my frustrations do not interfere with my care of the patient or my development of working relationships with the health care team.
- The patient is not discriminated against and neglected based on his inability to communicate and his decreased level of consciousness.
- On a professional developmental level, I explore my agency and role in patient advocacy while I have the support of and guidance from my clinical faculty; I learn to effectively navigate a complex, interprofessional situation.

Personal Learning: Here's to the Future!

Happy and sad outcome. Although this patient was not verbally communicating, I held his hand, talked to him, and felt that he was able to recognize my caring presence. After interprofessional rounds that morning, I verbalized my frustration about the status of my patient to my clinical instructor and I asked if she would come meet him and help me provide the necessary care. Unlike my nurse, my clinical instructor involved Mr. Everly in his care, providing verbal and tactile support and comfort as we worked to make him as comfortable as possible. She provided me tips and tricks as she walked Mr. Everly and me through the interventions. My instructor demonstrated how to provide personal care focused on protecting and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

maintaining the dignity of the patient. In addition, my instructor called in the charge nurse to point out the lack of care this patient had been receiving, wanting to ensure that his future level of care improved. My instructor and the charge nurse, in a professional, nondegrading way, expressed to the assigned nurse that this patient needed a higher quality of care due to his critical condition. Having my instructor agree with my concerns for this patient and address the nurse and charge nurse made me feel much better about the care my patient would then receive. I later told my teacher that I was frustrated because I felt all the nurse was concerned about was "giving all the medications and signing off on the right pages," when in fact talking to this patient, holding his hand, and making him more comfortable were definitely as important. Two days later the patient died. I was sad but so honored to have been able to care for him and hold his hand in his last days.

Although I think I should have gone to my clinical instructor immediately to explain the problem I was having, telling her was the right decision. My instructor took my concerns seriously and first helped me care for the patient, then went straight to the charge nurse to ensure proper skin and wound care for the patient. Finally, she was able to address the nurse without insulting her to make sure we were all on the same page about the care this patient needed, but had not been receiving. By speaking up, I was able to leave my clinical assignment feeling positive about my actions and advocating for this patient. I still felt frustrated with how he had been cared for and realized that all too often as care providers, we get too involved in the routine of charting, distributing medications, and so on, and can forget how important some simple measures are such as offering a gentle touch, positioning, providing hygiene and wound care, and just spending time with the patient. I take comfort in knowing that I contributed, in a very small way, to Mr. Everly's dying with dignity.

Carrie Staines, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? What factors might have affected the assigned nurse's response to the patient? Would the student have been affected by any of these same factors? Do you agree with the criteria to evaluate a successful outcome? Did the nursing student validate the rationale for the outcome? What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve the quality and safety of care for patients like Mr. Everly?

Patient-Centered Care: What evidence from the scenario would lead you to suspect that the patient is at risk for impaired skin integrity? What preventive measures might be appropriate? What measures might be appropriate to ensure therapeutic person-centered care?

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to improve to ensure that you communicate care provided and needed at each transition in care? What communication skills do you need to improve to ensure that you function as a member of the patient-care team? Can you think of other ways to respond? How can you frame advocating for the patient in a way that builds team relationships and promotes teamwork?

Safety/Evidence-Based Practice: What skills do you need to improve to ensure that patients in your care receive the best nursing care possible? What evidence in nursing literature provides guidance for decision making regarding care of this patient? What does this tell you about yourself and about the adequacy of your skills for professional practice? What, if any, ethical and legal principles were demonstrated by the nursing student's actions?

Informatics: Can you identify the essential information that must be available in Mr. Everly's electronic health record to support safe patient care and coordination of care? What information should be documented in the electronic health record regarding the student's assessment and interventions?

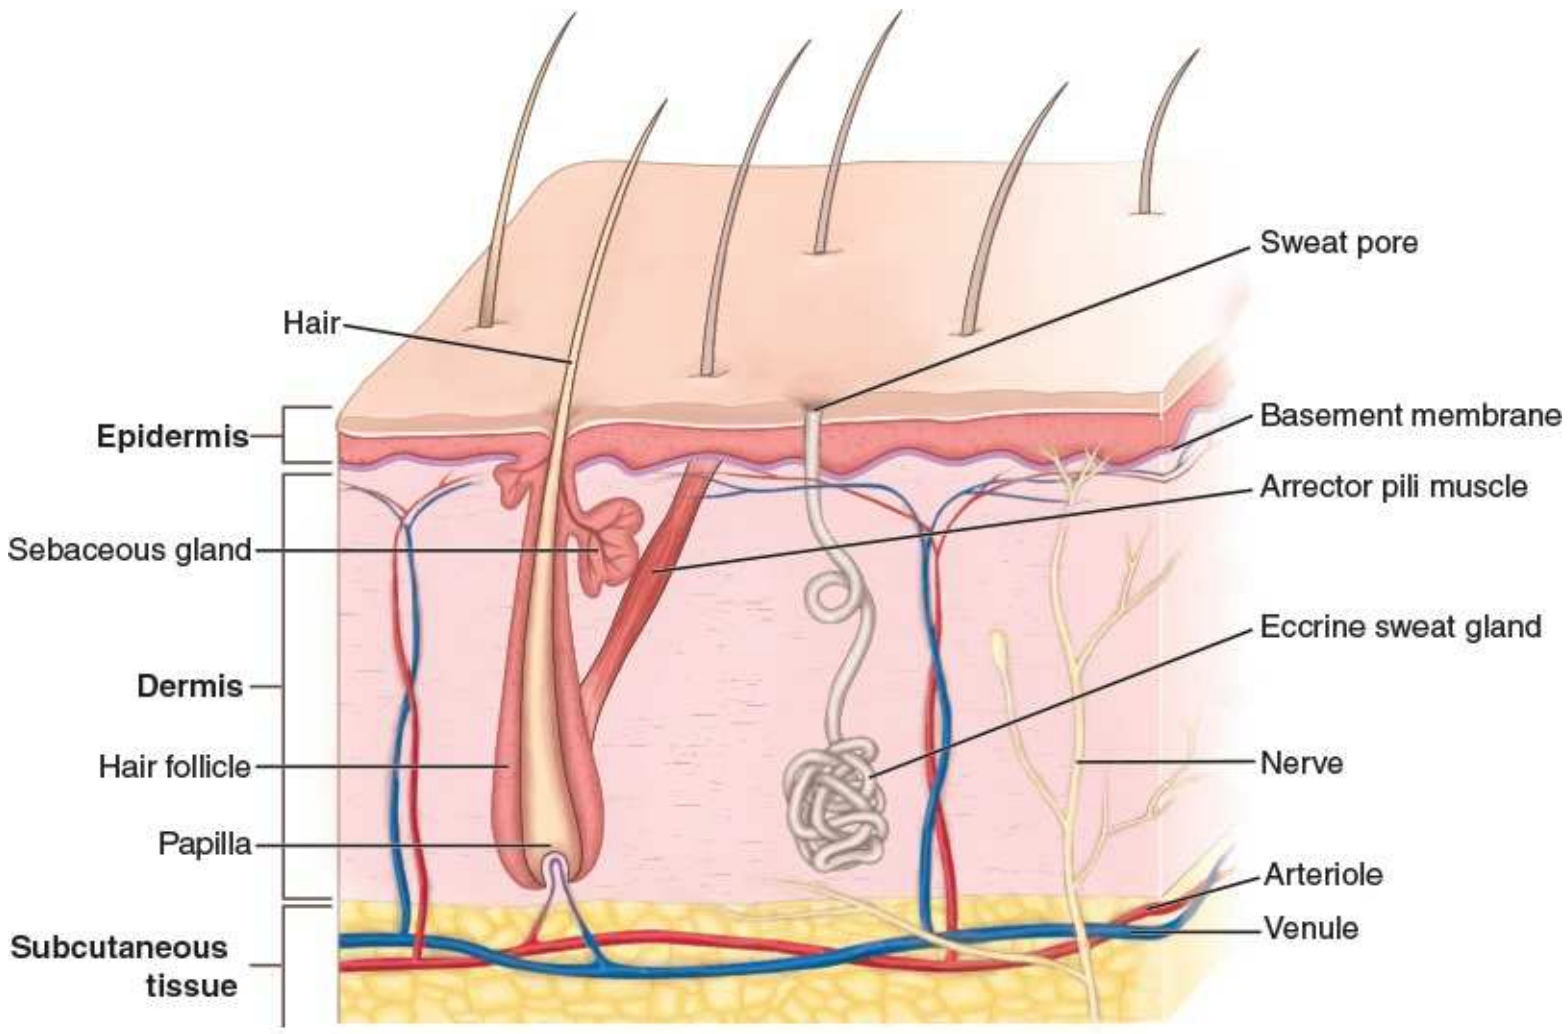

FIGURE 33-1. A cross section of normal skin.

Table 33-1 Functions of the Skin

FUNCTION	MECHANISMS
Protection	• Acts as a barrier to water, microorganisms, and damaging ultraviolet rays of the sun • Protects against infection • Protects against injury to underlying tissues and organs • Prevents loss of moisture from the surface and underlying structures
Temperature Regulation	• Draws heat from the skin as perspiration occurs and evaporates • Dissipates heat as blood vessels in the skin dilate • Compensates for cold conditions with the constriction of blood vessels in the skin to diminish heat loss • Compensates for cold through the contraction of pilomotor muscles that cause the hair to stand on end, forming a layer of air on the body for insulation (*gooseflesh* or *goose bumps*)
Psychosocial	• Contributes to the external appearance and is a major contributor to self-esteem • Plays an important role in identification and communication
Sensation	• Provides the sense of touch, pain, pressure, and temperature through millions of nerve endings • Allows the body to adjust to the environment through sensory impulses, in conjunction with the brain and spinal cord
Vitamin D Production	• Activated by ultraviolet rays from the sun to produce vitamin D
Immunologic	• Triggers immunologic responses when broken
Absorption	• Absorbs substances, such as medications, for local and systemic effects
Elimination	• Excretes small amounts of water, electrolytes, and nitrogenous wastes in sweat

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Factors Affecting Skin Integrity

Basic principles related to integrity of the skin and mucous membranes include the following:

- Unbroken and healthy skin and mucous membranes serve as the first lines of defense against harmful agents.
- Resistance to injury of the skin and mucous membranes varies among people. Factors influencing resistance include the person's age, the amount of underlying tissues, and comorbidities.
- Adequately nourished and hydrated body cells are resistant to injury. The better nourished the cell is, the better able it is to resist injury and disease.
- Adequate circulation is necessary to maintain cell life. When circulation is impaired for any reason, cells receive inadequate nourishment and cannot remove wastes efficiently.

Table 33-2 identifies some factors that place a patient at risk for skin alterations.

Developmental Considerations

Specific characteristics of the skin are associated with different developmental stages. Hygiene practices at every age have a direct influence on the status and appearance of the skin.

- In children younger than age 2 years, the skin is thinner and weaker than it is in adults.
- An infant's skin and mucous membranes are injured easily and are subject to infection. Careful handling of infants is required to prevent injury to and infection of the skin and mucous membranes.
- A child's skin becomes increasingly resistant to injury and infection.
- The structure of the skin changes as a person ages. In older adults, the maturation of epidermal cells is delayed, leading to thin, easily damaged skin. Circulation and collagen formation are impaired, leading to decreased elasticity and increased risk for tissue damage from pressure. Changes that occur in the skin with aging are discussed in the Focus on the Older Adult feature (on page 1154).

State of Health

The state of a person's health and therapeutic treatments have a direct effect on the condition of the skin. Proper nutrition, adequate circulation, and good overall health are important for healthy skin.

- Very thin and very obese people tend to be more susceptible to skin irritation and injury.
- Fluid loss through fever, vomiting, or diarrhea reduces the fluid volume of the body. This is termed *fluid volume deficit* or *dehydration* (depending on whether there are intracellular and/or intravascular and sodium losses) and makes the skin appear loose and flabby.
- Excessive moisture such as perspiration, often associated with being ill, predisposes the skin to breakdown, especially in skin folds. Excessive moisture may also occur as a result of bladder or bowel incontinence.
- Jaundice, a condition caused by excessive bile in lightly pigmented skin, results in a yellowish tinge to the skin and whites of the eyes. The skin is often itchy and dry; patients with jaundice are more likely to scratch their skin and cause an open lesion, with the potential for infection.
- Diseases of the skin, such as eczema and psoriasis, may have a genetic predisposition and often cause lesions that require special care.

Table 33-2 Factors Placing a Person at Risk for Skin Alterations

FACTOR	NURSING IMPLICATIONS
Age	See text discussion regarding developmental issues related to skin and the Focus on the Older Adult feature on page 1154.
Lifestyle Variables	
Occupation or other activity that gives a person prolonged exposure to the sun	• Places person at high risk for developing skin cancer, which has an excellent prognosis if detected and treated in its early stages, but which may be fatal if treatment is delayed. • Assessment needs to include careful examination of a sore that does not heal, or a change in size or color of a wart or mole.
Body piercing	• Potential interference with airway management. Potential risk for bacterial and viral infections, scarring, nerve damage, tissue trauma, and deformity. • Assess patient's knowledge of symptoms of infection at the site and when to seek medical care. • Assess piercing site(s) for redness, swelling, discharge, or excessive pain at the site.
Changes in Health State	

Dehydration or malnutrition	• If fluid, protein, and vitamin C intake is deficient, skin loses elasticity and becomes prone to breakdown. • Nursing care is directed toward preventing skin breakdown: frequent changes of patient's position with skin assessment at each change, special mattresses and protection of bony prominences, use of lotions, and attention to fluid and nutritional status.
Reduced sensation (paralysis, local nerve damage, circulatory insufficiency)	• Patient's inability to sense temperature extremes, pressure, friction, and other such factors can easily result in injury. • Nursing care incorporates special attention to safety.
Illness	
Diabetes mellitus Impaired immune system	• Numerous factors combine to cause skin problems in patients with diabetes: cuts and sores that do not heal, lesions on the lower extremities that ulcerate and become necrotic, and recurrent bacterial and fungal infections. • The patient with diabetes must be taught special hygiene measures to prevent trauma to the skin and learn to assess the skin carefully to detect any alteration. • Patients with diagnoses that involve an alteration of the immune system (HIV, diabetes, autoimmune disorders) are predisposed to the development of skin breakdown and infections. • Treatments for underlying conditions may also affect the immune response essential for skin protection and wound healing (immunosuppressants, radiation).
Diagnostic Measures	
Gastrointestinal (GI) series	• The GI cleansing preparations administered to patients having GI studies done may result in diarrhea, which irritates the sensitive skin in the perianal area—especially if the patient had bouts of diarrhea before the studies; anticipating the problem, noting redness and inflammation, and beginning warm baths and ointments are welcome nursing measures that patients may be too embarrassed to seek.
Therapeutic Measures	
Bed rest	• Bed rest predisposes patients to skin breakdown; the harsh detergents used on hospital laundry compound this problem. • Pressure points need to be examined frequently and protected.
Casts	• Casts easily irritate the skin; careful assessment, covering the rough edges of the cast, and skin care are indicated.
Aquathermia unit	• Wet heat has therapeutic benefit but, if applied to the skin for too long, may macerate the skin; follow protocol in length of application, examine skin carefully between treatments, and allow to dry.
Medications	• Medications may cause allergic skin reactions, such as rashes. • When evaluating the patient's response to a new drug, examine the skin for redness and itching.
Radiation therapy	• Radiation therapy exposes normal skin cells as well as cancer cells in treatment field to effects of radiation, with the potential for erythema and dry/wet desquamation (loss of skin integrity).

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES IN SKIN

Age-Related Changes	Nursing Strategies
Subcutaneous and dermal tissues become thin:	• Do not apply tape to skin unless necessary.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Skin is more easily injured.
- Skin has less capacity to insulate.
- Skin wrinkles more easily.
- Sensation of pressure and pain is reduced.

Activity of the sebaceous and sweat glands decreases:
- Skin becomes dryer.
- Pruritus (itching) may occur.

Cell renewal is shorter:
- Healing time is delayed.

Melanocytes (cells that make the pigment that colors hair and skin) decline in number:
- Hair becomes gray-white.
- Skin may be unevenly pigmented.

Collagen fiber is less organized:
- Skin loses elasticity.

- Check skin frequently to observe for any signs of a pressure injury.
- Pad bony prominences if necessary.
- Assess pressure tolerance by checking pressure points for redness after 30 minutes.
- Clean perineal area daily but do not bathe full body on a daily basis.
- Apply lotions and moisturizers as needed.
- Encourage adequate hydration.
- Eliminate the use of harsh soaps.
- Perform careful skin assessments, looking for signs of skin breakdown.
- Assist patient with skin checks, observing for any signs of melanoma or other skin abnormalities.
- Check skin frequently for tears, irritation, or breakdown.

WOUNDS AND PRESSURE INJURIES

A **wound** is a break or disruption in the normal integrity of the skin and tissues. That disruption may range from a small cut on a finger to a third-degree burn covering almost all of the body. Wounds may result from mechanical forces (such as surgical incisions) or physical injury (such as a burn). Examples of types of wounds and their causes are highlighted in Table 33-3.

Wound Classification

The etiology, or cause, of a wound is considered when developing the plan of care for a patient. In general, most wounds can be classified as either surgical (intentional, controlled, sterile), traumatic (may require additional intervention such as fluid administration or a tetanus shot), neuropathic or vascular (related to an underlying neurologic and/or circulatory issue), or pressure related (Baranoski & Ayello, 2020). The underlying cause must be addressed. For example, in a patient with a diabetic foot ulcer, healing and prevention of future ulcers is predicated on the treatment of the underlying diabetes and associated neuropathies and circulatory issues. Wounds may also be defined as open or closed and acute or chronic, based on whether the wound follows the normal, timely healing process or not. Pressure injuries may be further classified as: (1) partial thickness where all or a portion of the dermis is intact; (2) full thickness where the entire dermis, sweat glands, and hair follicles are severed, which can expose bone, tendon, or muscle; (3) unstageable, a full-thickness loss where the true depth cannot be determined, or (4) deep pressure-induced tissue damage (European Pressure Ulcer Advisory Panel [EPUAP], National Pressure Injury Advisory Panel [NPIAP], & Pan Pacific Pressure Injury Alliance [PPPIA], 2019a/2019b).

Think back to **Lucius Everly**, the patient who had abdominal surgery and is in the critical care unit. His postoperative treatments would necessitate the placement of one or more intravenous lines, which cause an intentional, controlled break in the skin. His abdominal incision would be considered a surgical wound. The nurse would incorporate an understanding of the principles of surgical asepsis when caring for these wound sites to prevent infection.

Open and Closed Wounds

An open wound occurs from intentional or unintentional trauma. The skin surface is broken, providing a portal of entry for microorganisms. Bleeding, tissue damage, an increased risk for infection, and delayed healing may accompany open wounds. Examples include incisions and abrasions.

A closed wound results from a blow, force, or strain caused by trauma such as a fall, an assault, or a motor vehicle

crash. The skin surface is not broken, but soft tissue is damaged, and internal injury and hemorrhage may occur. Examples include ecchymosis and hematomas.

Acute and Chronic Wounds

Acute wounds, such as surgical incisions, usually heal within days to weeks. The wound edges are well approximated (edges meet to close skin surface), and the risk of infection is low. Acute wounds usually progress through the healing process without interruption. Chronic wounds, in contrast, do not progress through the normal sequence of repair. The healing process is impeded. The wound edges are often not approximated, the risk of infection is increased, and the normal healing time is delayed (>30 days). Chronic wounds remain in the inflammatory phase of healing (discussed in the next section). Chronic wounds include any wound that does not heal along the expected continuum, such as wounds related to diabetes, arterial or venous insufficiency, and pressure injuries. Patients with chronic wounds report a diminished quality of life, chronic pain, and restricted mobility (sometimes related to the loss of a limb) and may even die because of their wound (Baranoski & Ayello, 2020; Hajhosseini et al., 2020).

Table 33-3 Types of Wounds

TYPE	CAUSE
Incision	Cutting or sharp instrument; wound edges well approximated and aligned; surrounding tissue undamaged; bleeds freely and least likely to become infected
Contusion	Blunt instrument, overlying skin remains intact, with injury to underlying soft tissue; possible resultant bruising and/or hematoma
Abrasion	Friction; rubbing or scraping epidermal layers of skin; top layer of skin scraped away; dirt and germs often embedded and can become infected
Laceration	Tearing of skin and tissue with blunt or irregular instrument; tissue not aligned, often with loose flaps of skin and tissue; frequently contaminated with dirt or other material ground into the wound and likely to become infected
Puncture	Blunt or sharp instrument puncturing the skin; intentional (such as venipuncture) or accidental; consider penetrating object when considering infection probability
Penetrating	Foreign object entering the skin or mucous membrane and lodging in underlying tissue; fragments possibly scattering throughout tissues
Avulsion	Tearing a structure from normal anatomic position; possible damage to blood vessels, nerves, and other structures
Chemical	Toxic agents such as drugs, acids, alcohols, metals, and substances released from cellular necrosis
Thermal	High or low temperatures; cellular necrosis as a possible result
Irradiation	Ultraviolet light or radiation exposure; can cause wet or dry desquamation
Pressure ulcers	Compromised circulation secondary to pressure or pressure combined with friction; classified by *Stages 1–4*, *Unstageable*, and *Deep Tissue* injury
Venous ulcers	Injury and poor venous return, resulting from underlying conditions, such as incompetent valves or obstruction; frequently have significant drainage; compression essential (after arterial flow verified)
Arterial ulcers	Injury and underlying ischemia, resulting from a lack of blood flow to the lower extremities secondary to conditions such as atherosclerosis or thrombosis; many have black eschar; increasing blood flow essential for treatment
Diabetic ulcers	Injury and underlying diabetic neuropathy, peripheral arterial disease, diabetic foot structure; located below the ankle

Wound Healing

Wound healing is a process of tissue response to injury. Injured tissues are repaired by physiologic mechanisms that regenerate functioning cells and replace connective tissue cells with scar tissue. The healing process fills the gap caused by tissue destruction, restoring the structural integrity of the damaged tissue through the orderly release of growth factors and chemical mediators (Norris, 2019). These substances help to increase the blood supply to the damaged area, wall off and remove cellular and foreign debris, and initiate cellular development.

Normally, the healing process occurs without assistance. However, interventions can help to support the process. For example, tissue healing is promoted by keeping the injured area free of debris through proper cleaning. Positioning the wounded area to promote circulation to that part helps to promote tissue healing. These interventions are based on the principles of wound healing outlined in Box 33-1 on page 1156.

Wound repair occurs by primary intention, secondary intention, or tertiary intention. Wounds healed by primary intention are well approximated (skin edges tightly together). Intentional wounds with minimal tissue loss, such as those made by a surgical incision with sutured approximated edges, usually heal by primary intention. Wounds healed by secondary intention have edges that are not well approximated. Large, open wounds, such as from burns or major trauma, which require more tissue replacement and are often contaminated, commonly heal by secondary intention. If a wound that is healing by primary intention becomes infected, it will heal by secondary intention. Wounds that heal by secondary intention take longer to heal and form more scar tissue (Norris, 2019). Connective tissue healing and repair follow the same phases in healing. However, differences occur in the length of time required for each phase and in the extent of new tissue formed. Wounds healed by tertiary intention, or delayed primary closure, are those wounds left open for several days to allow edema or infection to resolve or fluid to drain, and then are closed.

Box 33-1 Principles of Wound Healing

- Intact skin is the first line of defense against microorganisms. A break in the integrity of the skin increases the risk for infection. Careful hand hygiene before caring for a wound is probably the single most effective method for preventing wound infections.
- The body responds systemically to trauma in any of its parts. For example, a surgical incision can cause a variety of systemic reactions, including increased body temperature, increased heart and respiratory rates, anorexia or nausea and vomiting, musculoskeletal tension, and hormonal changes.
- An adequate blood supply is essential for the body's normal response to any injury. The blood transports increased numbers of leukocytes, erythrocytes, and platelets to the site of injury. Antibodies are carried by the plasma. Increased circulation to the injured part removes toxins and debris and provides nutrients and oxygen. Areas of the body with a good blood supply, such as the head and the neck, heal faster than areas in which the blood supply is not as great, such as the distal part of an extremity.
- Normal healing is promoted when the wound is free of foreign material, such as excessive exudate, dead or damaged tissue cells, pathogenic organisms, or embedded fragments of bone, metal, glass, or other substances. In some situations, a collection of pus or foreign body is walled off and healing occurs around it to form an abscess.
- The ability to handle altered skin integrity depends on the extent of the damage and the person's general state of health. The capacity to deal adequately with a wound is limited when a healthy person sustains a massive injury, when the patient has a chronic illness or a depressed immune system, or when the patient is very young or very old.
- The body's response to a wound is more effective if proper nutrition has been maintained.
  - Undernourished patients are at greater risk for developing a wound infection because they have difficulty mounting their cell-mediated defense system associated with T-lymphocyte activity, and some leukocytic functions are diminished in the presence of protein deficiency.
  - Although the role of fatty acids in wound healing is not well understood, certain quantities of glucose are necessary to meet the energy requirements for wound healing.
  - Various vitamins, minerals, and trace elements are also needed for efficient wound healing. Vitamin A is necessary for collagen synthesis and epithelialization. Vitamin B complex serves as a cofactor of enzyme reactions needed for wound healing. Vitamin C is needed for collagen synthesis, capillary formation, and resistance to infection. Vitamin K is needed for the synthesis of prothrombin. Zinc,

copper, and iron assist in collagen synthesis. Manganese serves as an enzyme activator.

Phases of Wound Healing

The wound healing process can be divided into three or four phases, depending on the reference. In this chapter, four phases will be discussed: hemostasis, inflammation, proliferation, and maturation. These four phases systematically lead to repair of the injury (Baranoski & Ayello, 2020). If three stages are identified, hemostasis is included as part of the inflammatory stage (Norris, 2019).

HEMOSTASIS

Hemostasis occurs immediately after the initial injury primarily to stop the bleeding and activate the white blood cells to fight any invading bacteria. Involved blood vessels constrict and blood clotting begins through platelet activation and clustering. This coagulation results in the formation of a fibrin clot. The temporary clot forms, then the body releases substances that dissolve the clot (fibrinolysis) and stimulate other cells to migrate to the injury to participate in the other phases of healing (Baranoski & Ayello, 2020; Corum, 2019; Norris, 2019).

INFLAMMATORY PHASE

The inflammatory phase follows hemostasis and lasts about 2 to 3 days. White blood cells (WBCs), predominantly leukocytes and macrophages, move to the wound. Leukocytes arrive first to ingest bacteria and cellular debris. About 24 hours after the injury, macrophages (a larger phagocytic cell) enter the wound area and remain for an extended period. Macrophages are essential to the healing process. They not only ingest debris, but also release growth factors that are necessary for the growth of epithelial cells and new blood vessels. These growth factors also attract fibroblasts that help to fill in the wound, which is necessary for the next stage of healing. After a brief period of constriction during homeostasis, the blood vessels dilate and capillary permeability increases, allowing plasma and blood components to leak out into the area that is injured, forming a liquid called **exudate**. The accumulation of exudate and the increased perfusion result in acute inflammation, which is characterized by pain, heat, redness, and swelling at the site of the injury. Cytokines promote the repair process by increasing the inflammatory response. During the inflammatory phase, the patient has a generalized body response, including a mildly elevated temperature, leukocytosis (increased number of WBCs in the blood), and general malaise (Baranoski & Ayello, 2020; Corum, 2019; Norris, 2019).

PROLIFERATION/REPAIR PHASE

The proliferation phase, also known as the repair, fibroblastic, regenerative, or connective tissue phase, encompasses the processes that result in actual healing. The proliferation phase lasts for several weeks. New tissue is built to fill the wound space, primarily through the action of fibroblasts. Fibroblasts are connective tissue cells that synthesize and secrete collagen and produce specialized growth factors responsible for inducing blood vessel formation as well as increasing the number and movement of endothelial cells. Capillaries grow across the wound, bringing oxygen and nutrients required for continued healing. Fibroblasts form fibrin that stretches through the clot. A thin layer of epithelial cells forms across the wound, and blood flow across the wound is reinstituted. The new tissue, called **granulation tissue**, forms the foundation for scar tissue development. It is highly vascular, red, and bleeds easily. In wounds that heal by first intention, epidermal cells seal the wound within 24 to 48 hours, thus the granulation tissue is not visible.

Collagen synthesis and accumulation continue, peaking in 5 to 7 days. Depending on the size of the wound, collagen deposit continues for several weeks or even years. By the end of the second week following the injury, most WBCs have left the wound area, and the wound is lighter in color. The systemic symptoms now typically disappear. During this phase, adequate nutrition, and oxygenation, as well as prevention of strain on the suture line, are important patient care considerations.

Wounds that heal by secondary intention eventually follow the same process but take longer to heal and form more scar tissue. Granulation tissue fills the wound and is then covered by skin cells that grow over the granulation tissue. Connective tissue healing and repair follow the same phases in healing. However, differences occur in the length of time required for each phase and in the extent of granulation tissue formed (Baranoski & Ayello, 2020; Corum, 2019; Norris, 2019).

MATURATION/REMODELING PHASE

The final stage of healing, maturation (or remodeling) begins about 3 weeks after the injury, possibly continuing for months or years. Collagen that was haphazardly deposited in the wound is remodeled, making the healed wound stronger and more like adjacent tissue. New collagen continues to be deposited, which compresses the blood vessels in the healing wound, so that the **scar** (avascular collagen tissue that does not sweat, grow hair, or tan in sunlight) eventually becomes a flat, thin line. Scar tissue is less elastic than uninjured tissue. The strength of the scar tissue remains less (70% to 80%) than that of normal tissue, even many years following injury, and it is never fully restored. Wounds that heal by secondary intention take longer to remodel and form a scar smaller than the original wound. If the scar is over a joint or other body structure, it may limit movement and cause disability (Baranoski & Ayello, 2020; Corum, 2019; Norris, 2019).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Recall **Sam Bentz**, the 56-year-old admitted for treatment of a bone infection. The nurse would apply the knowledge about the phases of wound healing when reviewing this patient's past history, especially with respect to the wounds that developed during his last hospital admission. In addition, this knowledge would help form the basis for the patient's care plan should another wound occur during this hospitalization.

Factors Affecting Wound Healing

A variety of factors affect wound healing. Local factors, those occurring directly in the wound, include pressure, **desiccation** (dehydration), **maceration** (overhydration), trauma, edema, infection, excessive bleeding, **necrosis** (death of tissue), and the presence of **biofilm** (a thick grouping of microorganisms). Systemic factors, those occurring throughout the body, include age, circulation to and oxygenation of tissues, nutritional status, wound etiology, general health status and disease state, immunosuppression, proinflammatory conditions and extent of systemic inflammation, medication use and other therapies, and adherence to treatment plan (Baranoski & Ayello, 2020; Beyene et al., 2020; Norris, 2019).

LOCAL FACTORS

Factors occurring local to the wound itself can prolong wound healing. These factors are discussed in the following sections.

Pressure

Pressure disrupts the blood supply to the wound area. Persistent or excessive pressure interferes with blood flow to the tissue and delays healing.

Desiccation

Desiccation is the process of drying up. Cells dehydrate and die in a dry environment. This cell death causes a crust to form over the wound site and delays healing. Wounds that are kept moist (not wet) and hydrated experience enhanced epidermal cell migration, which supports **epithelialization** (epithelial cells form a new surface layer) and neovascularization (formation of new blood vessels; Hess, 2019).

Maceration

Maceration, tissue erosion, results from prolonged exposure to moisture. Overhydration of cells related to urinary and fecal incontinence can also lead to maceration and impaired skin integrity. This damage is related to moisture, changes in the pH of the skin, overgrowth of bacteria and infection of the skin, and erosion of skin from friction on moist skin. Moisture-associated skin damage (MASD) may be caused by drainage from the wound itself and can result in maceration of the areas surrounding the wound (Baranoski & Ayello, 2020).

Trauma

Repeated trauma to a wound area results in delayed healing or the inability to heal.

Edema

Edema at a wound site interferes with the blood supply to the area, resulting in an inadequate supply of oxygen and nutrients to the tissue.

Infection

Bacteria in a wound increase stress on the body, requiring increased energy to deal with the invaders. Infection requires large amounts of energy be spent by the immune system to fight the microorganisms, leaving little or no reserves to attend to the job of repair and healing. In addition, toxins produced by bacteria and released when bacteria die interfere with wound healing and cause cell death.

Excessive Bleeding

Excessive bleeding results in large clots. Large clots increase the amount of space that must be filled during healing and interferes with oxygen diffusion to the tissue. In addition, accumulated blood or drainage of any type is an excellent place for growth of bacteria and promotes infection (Baranoski & Ayello, 2020).

Necrosis

Dead tissue present in the wound delays healing. Dead tissue appears as slough—moist, yellow, stringy tissue—and **eschar** appears as dry, black, leathery tissue. Healing of the wound will not take place with necrotic tissue in the wound. Mechanical or chemical removal of the dead tissue must occur for healing to begin (Baranoski & Ayello, 2020; Hess,

2019).

Biofilm

Wound biofilms are the result of wound bacteria growing in clumps, embedded in a thick, self-made, protective, slimy barrier of sugars and proteins. This barrier contributes to decreased effectiveness of antibiotics against the bacteria (antibiotic resistance) and decreases the effectiveness of the normal immune response by the patient (Baranoski & Ayello, 2020). The bacteria also produce a protective matrix that attaches the biofilm to the wound surface. Biofilms impair wound healing and contribute to chronic wound inflammation and wound infection (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a/2019b; Hess, 2019).

SYSTEMIC FACTORS

Factors not related to the wound itself also can prolong wound healing. These factors are discussed in the following sections.

Age

The major skin layers arise from different embryologic origins, resulting in poor adherence between the epidermis and the dermis. This loose binding between the layers causes the layers to separate easily during an inflammatory process, placing infants and small children at risk for impaired skin integrity. Epidermal stripping, the unintentional removal of the epidermis with tape removal, is one type of such injury. Care should be taken to minimize tension, traction, and wrinkles on the skin when using tape on these young patients.

Children and healthy adults, however, heal more rapidly than do older adults, in whom physiologic changes caused by aging result in diminished fibroblastic activity and circulation. Older adults are more likely to have one or more chronic illnesses, with pathologic changes that impede the healing process. See the accompanying Focus on the Older Adult display for other age-related factors affecting wound healing.

Circulation and Oxygenation

Adequate blood flow to deliver nutrients and oxygen and to remove local toxins, bacteria, and other debris is essential for wound healing. Certain physical conditions, because of their effect on circulation and oxygenation, can affect wound healing. Circulation may be impaired in older adults and in people with peripheral vascular disorders, cardiovascular disorders, hypertension, or diabetes mellitus. Oxygenation of tissues is decreased in people with anemia or chronic respiratory disorders and in those who smoke.

Recall **Lucius Everly**, the patient described in the Reflective Practice display. The nurse's ability to integrate knowledge of the effects of diabetes on circulation would be important in planning measures to ensure adequate circulation to his extremities as a means to prevent skin breakdown.

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES IN WOUND HEALING

Age-Related Changes	Nursing Interventions
Skin loses turgor and is more fragile.	• Maintain hydration with intravenous fluids as prescribed. • Maintain record of intake and output. • Use caution when removing tape.
Decreased secretion of enzymes and absorption of nutrients and minerals may increase risk for delayed wound healing.	• Maintain intake of adequate kilocalories with oral, enteral, or parenteral feedings. • Ensure that diet is high in protein, vitamin A, vitamin C, and trace elements (zinc and copper). • Monitor lab results such as serum albumin, total protein.
Risk of infection increases from: • Slower inflammatory response. • Reduced antibody production and endocrine	• Maintain careful hand hygiene and surgical asepsis with dressing changes and care of tubes or drains.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

system function.
- Increased incidence of chronic illnesses, such as diabetes mellitus and cardiovascular disease, that compromise circulation and tissue oxygenation.

- Take and record vital signs, noting and reporting increased temperature.
- Monitor wound for manifestations of infection.
- Administer medications as prescribed.
- Administer supplemental oxygen as prescribed.

Large amounts of subcutaneous and tissue fat (which has fewer blood vessels) results in hypoperfusion and hypovascularity. This impaired oxygenation and perfusion leads to an alteration in cellular repair processes and the response of immune cells. People with obesity more frequently have tension on their wound edges that can result in wound dehiscence. Skin folds harbor bacteria and provide a moist environment well suited for the spread of fungal and bacterial infections. Skin-on-skin friction causes ulceration and is more common in people with obesity (Avishai et al., 2017).

Nutritional Status

Wound healing requires adequate proteins, carbohydrates, fats, vitamins, and minerals. Calories and protein are necessary to rebuild cells and tissues. Vitamins A and C are essential for epithelialization and collagen synthesis. Zinc plays a role in proliferation of cells. Fluids are necessary for optimal function of cells. All phases of the wound healing process are slowed or inadequate in the patient with poor nutritional status and fluid imbalance.

Some patients with obesity suffer from protein malnutrition, which interferes with healing. Patients who are undernourished may lack the nutritional stores to promote wound healing. Nutrition is further discussed in Chapter 37.

Wound Etiology (Cause)

Knowing the etiology (cause) of a wound directly impacts on assessment and treatment of the wound (Baranoski & Ayello, 2020). It may also indicate the general health status of the patient and the associated likelihood of future wounds. For example, a wound that stems from a decrease in arterial blood flow to the extremities, a systemic issue, may recur; however, a wound from a spider bite may be a one-time event.

The COVID-19 pandemic brought about two distinct etiologies: (1) unavoidable pressure injury, and (2) injury to baseline healthy heath care providers due to personal protective equipment (PPE). For patients, the hypercoagulable state inherent in COVID-19 resulted in skin changes that often appeared to be deep tissue pressure injury but were not. There was also an increase in the rate of deterioration and inability to prevent pressure injury in this critically ill population. This was compounded by multiorgan dysfunction, nutritional challenges, hemodynamic instability, proning and other position requirements, and the prolonged recovery period for some patients. Resource limitations and the shift to crisis care contributed to the inability of the interprofessional team to adhere to protocols and provide adequate classification of these microvascular-based injuries. Careful consideration needs to be given to resources and pressure injury prevention protocols during crisis situations (NPAIP, n.d.).

Nurses and other members of the interprofessional team also experienced unexpected skin injury during the COVID-19 pandemic. Although the benefits of wearing PPE far outweighed the risks, incorrectly worn PPE resulted in facial injury to health care professionals. Early in the pandemic, the NPIAP (2021) evidence-based recommendations included:

> (1) Prepare the skin before and after wearing PPE with skin sealants, barrier creams and moisturizers; (2) Frequent PPE offloading to relieve pressure and shear applied to the skin; (3) treat visible skin injuries immediately caused by PPE to minimize future infection; (4) non-porous dressings may provide additional skin protection, but lack current evidence; (5) health systems sound take care to educate frontline healthcare staff about placement and personal hygiene related to handling PPE (p. 5).

Nursing Self-Care Alert

Although the benefits of wearing a mask far outweighed the potential risks, nurses (and other members of the interprofessional health care team) had to take extra measures during the pandemic to protect their skin from breakdown due to prolonged use of masks and other necessary PPE.

Although these recommendations are evidence based, they need to be considered in the context of this crisis and include clinical judgment. Reflection on the pandemic is likely to result in additional practical, evidence-based recommendations, and drive the need for additional research on preventing PPE-related injuries (NPIAP, 2021).

Medications and Other Therapies

Patients who are taking corticosteroids or require postoperative radiation therapy are at high risk for delayed healing and wound complications. Corticosteroids decrease the inflammatory process, which may delay healing. Radiation depresses bone marrow function, resulting in decreased leukocytes and an increased risk of infection. The presence of a chronic illness (such as cardiovascular disease or diabetes mellitus) or impaired immune function can impair wound healing. Chemotherapeutic agents impair or stop proliferation of all rapidly growing cells, including cells involved in wound healing. Prolonged antibiotic therapy increases a patient's risk for secondary infection and superinfection.

Immunosuppression or Proinflammatory Conditions

Suppression of the immune system as a result of disease (e.g., HIV, lupus), medication (e.g., chemotherapy), or age (e.g., changes associated with advancing age) can delay wound healing. Proinflammatory conditions (e.g., vasculitis or rheumatoid arthritis) result in the release of proinflammatory cytokines, which prolong the inflammatory process (Baranoski & Ayello, 2020).

Adherence to Treatment Plan

Wound treatment plans will be discussed later in this chapter. Nonadherence to the treatment plan can negatively impact wound healing (Baranoski & Ayello, 2020). Fayne et al. (2020) explore the concept of *social genomics*, which considers the impact of social factors and processes on genome activity, as it relates to wound healing. Critical elements related to social determinants of heath and stress potentially directly (epigenetics, gene expression) or indirectly affect wound healing and, ultimately, impact on an individual's quality of life. The direct and indirect costs of wound care affect a patient's ability to adhere to a prescribed plan of care.

Wound Complications

Wound complications include infection, hemorrhage, dehiscence, evisceration, and fistula. These complications increase the risk for generalized illness and death, lengthen the patient's need for health care interventions, and add to health care costs.

INFECTION

Wound infection results when the patient's immune system fails to control the growth of microorganisms. Microorganisms can invade a wound at the time of trauma, during surgery, or at any time after the initial wound occurs. A contaminated wound is more likely to become infected than one that is not contaminated. In addition, the risk of infection is increased in a surgical wound created during a procedure involving the intestines because the risk for contamination with fecal material is high. Wound infections also occur as a result of hospital-acquired infections (HAIs). Symptoms of wound infection usually become apparent within 2 to 7 days after the injury or surgery; often, the patient is at home. Symptoms of infection include purulent drainage; increased drainage, pain, redness, and swelling in and around the wound; increased body temperature; and increased WBC count. Additional signs and symptoms include delayed healing and discoloration of granulation tissue in the wound (Baranoski & Ayello, 2020). In patients with infection in a chronic wound, pain and delayed healing may be the only symptoms (Baranoski & Ayello, 2020). Wound infections impair healing. Wound infections can lead to other complications, including development of chronic wounds, osteomyelitis (bone infection) and sepsis (presence of pathogenic organisms in the blood or tissues). See Box 33-2 for two helpful mnemonics to help you assess whether a patient has a wound infection (STONEES) or if the wound has undergone critical colonization (NERDS).

Box 33-2 Assessment of Degree of Wound Infection

Assessment of ≥3 signs/symptoms from the following list indicates superficial critical colonization:

NERDS

Nonhealing wound
Exudative wound
Red and bleeding wound
Debris in the wound
Smell from the wound

Assessment of ≥3 signs/symptoms from the following list indicates infection:

STONEES

Size is bigger
Temperature increased
OS—exposed bone
New areas of breakdown
Exudate
Erythema, **E**dema
Smell

HEMORRHAGE

Hemorrhage may occur from a slipped suture; a dislodged clot at the wound site; infection; or the erosion of a blood vessel by a foreign body, such as a drain. Check the dressing and the wound under the dressing, as possible, frequently

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

the first 48 hours after the injury. Surgical sites and other wounds should be routinely checked at least every 8 hours and with position changes. If excessive bleeding does occur, additional pressure dressings or packing may be necessary, fluid replacement will be considered, and surgical intervention may be required. Internal hemorrhage causes the formation of a **hematoma**, a localized mass of usually clotted blood (Stedman, n.d.). If the bleeding leads to a large accumulation of blood, it can put pressure on surrounding blood vessels and cause tissue ischemia (deficiency of blood to an area). See Chapter 31 for more information about hemorrhage.

DEHISCENCE AND EVISCERATION

Dehiscence and evisceration (Fig. 33-2) are the most serious postoperative wound complications. **Dehiscence** is the partial or total separation of wound layers as a result of excessive stress on wounds that are not healed. **Evisceration** is the most serious complication of dehiscence. It occurs primarily with abdominal incisions (Baranoski & Ayello, 2020; Hinkle et al., 2022). In evisceration, the abdominal wound completely separates, with protrusion of viscera (internal organs) through the incisional area. Patients at greater risk for these complications include those who are obese or malnourished, smoke tobacco, use anticoagulants, have infected wounds, or experience excessive coughing, vomiting, or straining (Hinkle et al., 2022). An increase in the flow of (serosanguineous) fluid from the wound between postoperative days 4 and 5 may be a sign of an impending dehiscence. The patient may say that "something has suddenly given way." If dehiscence occurs, cover the wound area with sterile towels moistened with sterile 0.9% sodium chloride solution and notify the health care provider. Once dehiscence occurs, the wound is managed like any open wound. Dehiscence with evisceration of an abdominal incision is a medical emergency. Place the patient in the low Fowler's position and cover the exposed abdominal contents, as discussed previously, being sure to keep the exposed viscera moist. Do not leave the patient alone, and be sure to provide reassurance and intravenous pain medications as appropriate. Notify the primary care provider immediately. This situation is an emergency that requires prompt surgical repair, so the patient should be kept NPO (Baranoski & Ayello, 2020; Hinkle et al., 2022). Dehiscence results in a scary situation for a patient and those close to them. Consider the poem from Dr. Haddad and reflect on the patient experience.

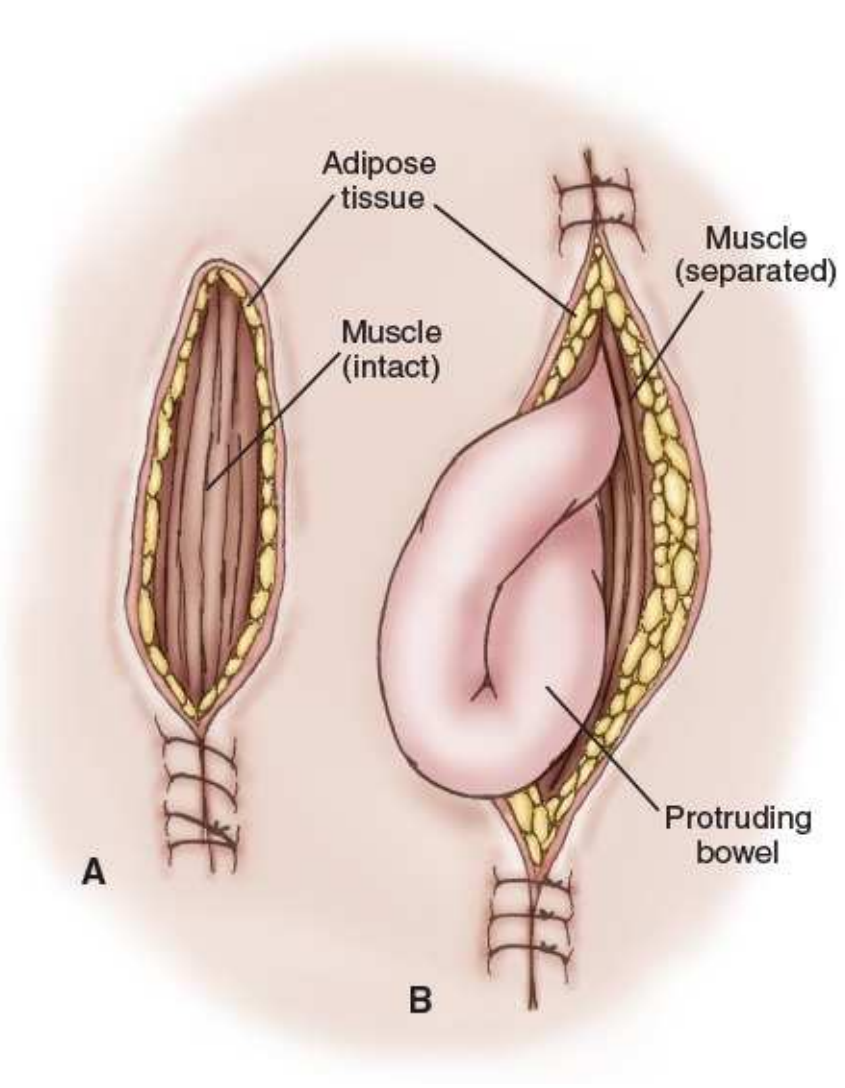

FIGURE 33-2. Wound complications. **A.** Dehiscence. **B.** Evisceration.

FISTULA FORMATION

A **fistula** is an abnormal passage from an internal organ or vessel to the outside of the body, or from one internal organ or vessel to another. Fistulas may be created purposefully; for example, an arteriovenous (AV) fistula is created surgically to provide circulatory access for kidney dialysis. However, fistula formation is often the result of infection that has developed into an **abscess**, which is a collection of infected fluid that has not drained. Accumulated fluid applies pressure to surrounding tissues, leading to the formation of the unnatural passage between two visceral organs or an organ and the skin (Baranoski & Ayello, 2020). Figure 33-3 illustrates a rectovaginal fistula, which is an abnormal connection between the rectum and vagina. The presence of a fistula increases the risk for delayed healing, additional infection, fluid and electrolyte imbalances, and skin breakdown.

Pressure Injury

A **pressure injury** is defined as localized damage to the skin and underlying tissue that usually occurs over a bony prominence or is related to the use of a (medical or other) device (Edsberg et al., 2016). The National Pressure Injury Advisory Panel (Edsberg et al., 2016) recently updated their staging definitions, and the term **pressure ulcer** was replaced by **pressure injury** to better-represent the early stages of pressure injury where there is not an actual ulcer or break in the skin. A pressure injury may be acute or chronic. Most pressure injuries develop when soft tissue is compressed between a bony prominence and an external surface for a prolonged period of time, or when soft tissue undergoes pressure in combination with shear stress and/or friction (NPIAP, 2016a; EPUAP, NPIAP, & PPPIA, 2019b). The terms *decubitus ulcer, pressure sore,* and *bedsore* are also used to refer to this type of wound.

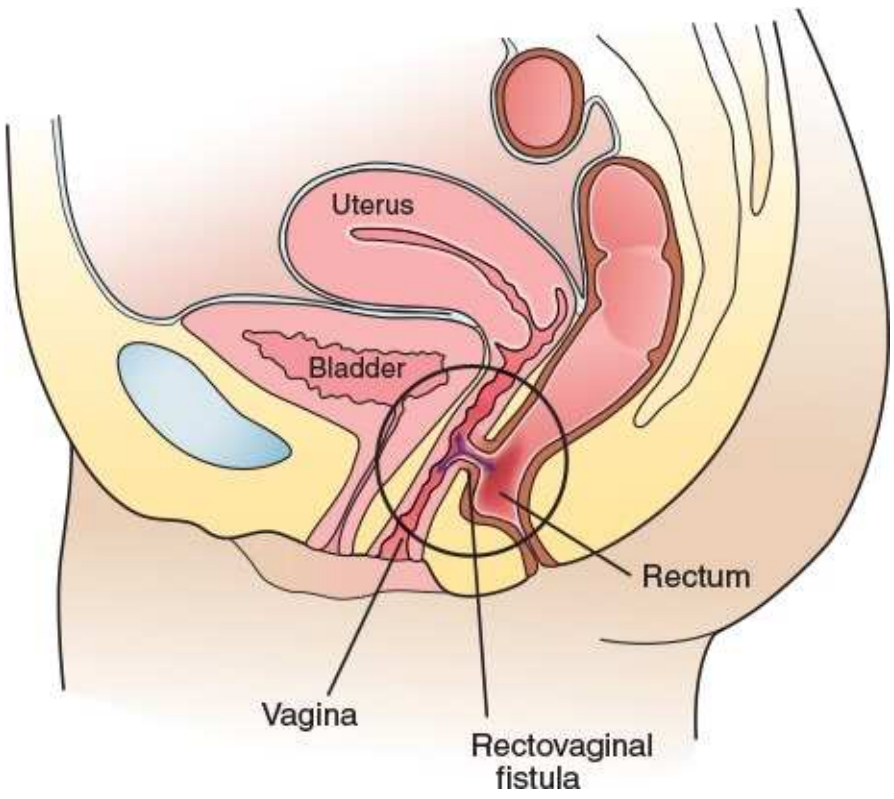

FIGURE 33-3. Fistula.

Poetry Nook

Dehiscence

You have come unstitched.

Holes appear on your threadbare abdomen.
Tunnels develop and connect bowel, liver, pancreas.
Enzymes ooze out and digest your skin,
no matter how hard we try to stem the flow.
A jerry-rigged system to
hold together our mistakes.
The stench is overwhelming, ever present
reminding everyone, but especially you,
that you have come undone. Since the truth is too horrible to grasp,

since I can offer you nothing else,
I clean you up.
I wash your face,
brush your teeth,
comb your hair,
turn you on your side,
push soiled linens away,
roll clean sheets under you,
remove layers and layers of damp dressings,
and replace them with new dressings and tape.

I give you the certainty and calmness of my motions,
the competence and comfort of my touch
as I smooth the top sheet over my work.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Done.

For a few pristine moments, we allow ourselves
to be caught in the illusion of your wholeness.

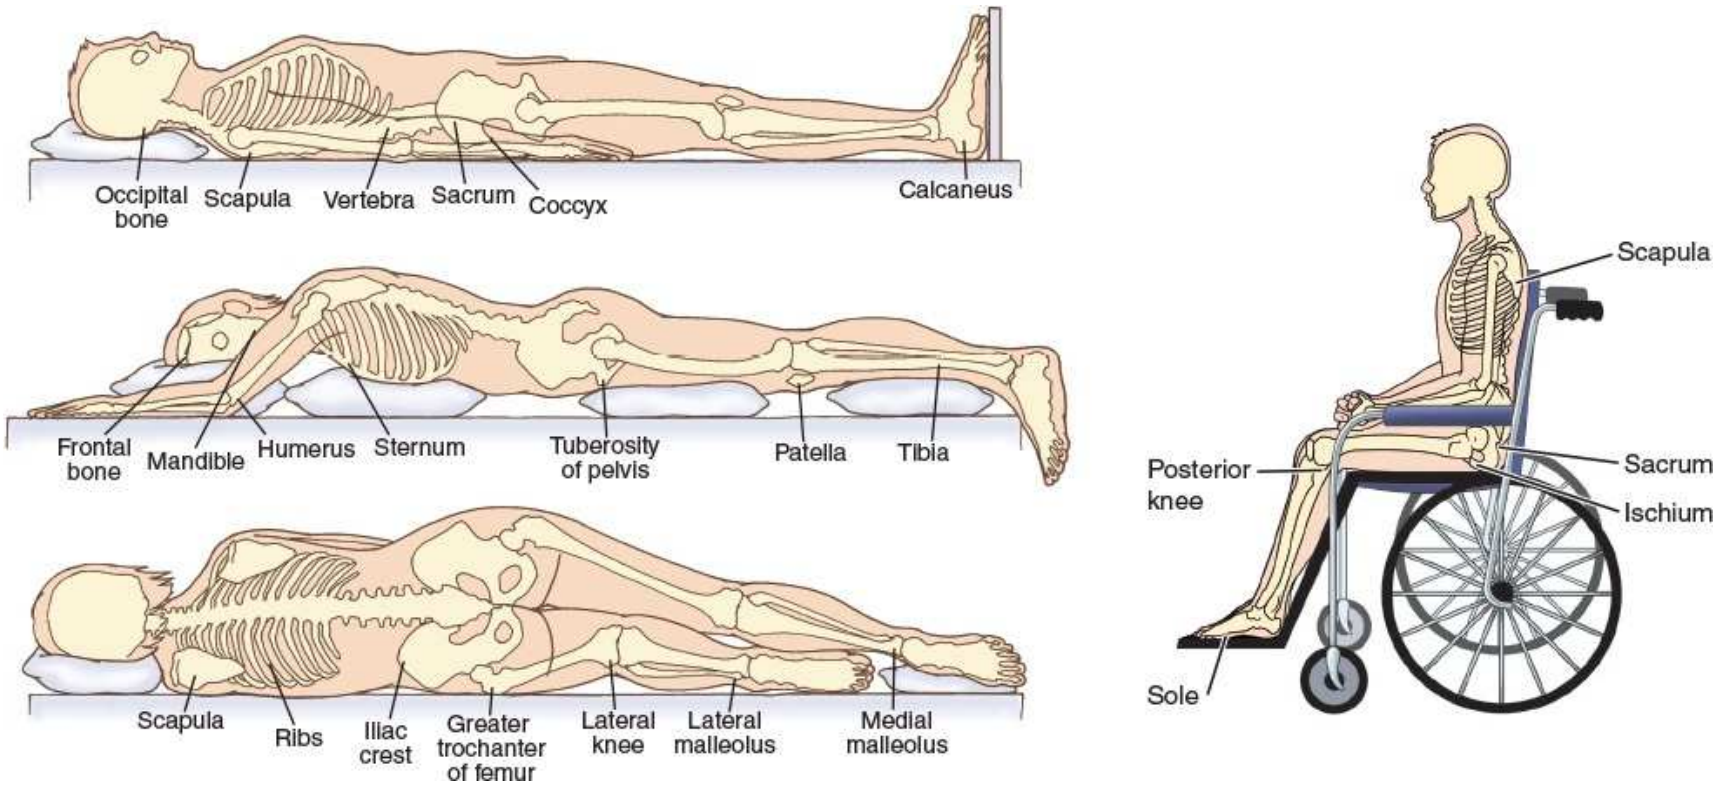

FIGURE 33-4. Common sites for development of pressure injuries.

Concept Mastery Alert

Pressure injury is the current term that refers to what was previously known as a *pressure ulcer*.

Pressure injuries are costly in terms of patient discomfort, disfigurement, decreased quality of life, and health care expenditures (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019b). Most pressure injuries occur in older adults as a result of a combination of factors, including aging skin, chronic illnesses, immobility, malnutrition, fecal and urinary incontinence, and altered level of consciousness. Other significant at-risk populations include people with spinal cord injuries, traumatic brain injuries, or neuromuscular disorders where sensory perception may be altered. When pressure injuries occur, aggressive intervention and treatment can spare the patient unnecessary pain and discomfort, prevent further tissue deterioration, hasten wound healing, and save millions of health care dollars. It is important to keep in mind that "some pressure injuries are unavoidable despite provision of evidence-based care by the health care team" (NPIAP, 2017, p. 3).

Factors in Pressure Injury Development

Pathologic changes at a pressure injury site result from blood vessel collapse caused by pressure, usually from body weight. Necrosis eventually occurs, leading to the characteristic ulcer. Three mechanisms contribute to pressure injury development: (1) external pressure that compresses blood vessels, (2) friction and shearing forces that tear and injure blood vessels and abrade the top layer of skin, and (3) microclimate of the skin related to temperature and moisture on the skin (Corum, 2019).

EXTERNAL PRESSURE

Pressure injuries usually occur over bony prominences where body weight is distributed over a small area without much subcutaneous tissue to cushion damage to the skin. Common sites for pressure injuries are illustrated in Figure 33-4. Of the susceptible areas, most pressure injuries occur over the sacrum and coccyx, followed by the trochanter (hip) and the calcaneus (heel).

The major predisposing factor for a pressure injury is external pressure applied over an area, which results in occluded blood capillaries and poor circulation to tissues. Insufficient circulation deprives tissue of oxygen and nutrients, which leads to **ischemia** (deficiency of blood in a particular area), hypoxia (inadequate amount of oxygen available to cells), edema, inflammation, and, ultimately, necrosis and ulcer formation. A pressure injury may occur in as little as 1 to 2 hours if the patient has not moved or been repositioned to allow circulation to flow to dependent areas. Patients with casts, orthopedic devices, or support stockings require routine assessment of areas where inadequate circulation may be a contributing factor to the development of a pressure injury.

Consider **Mr. Everly**, the postoperative patient in the critical care unit described in the Reflective Practice display. The nurse would integrate knowledge of the patient's condition, including his decreased level of consciousness and confinement in bed, to plan measures such as a turning schedule, proper positioning, and activities to promote movement in bed, thereby preventing body parts from exposure to prolonged pressure.

FRICTION AND SHEAR

Friction occurs when two surfaces rub against each other. The injury, which resembles an abrasion, can also damage superficial blood vessels directly under the skin. A patient who lies on wrinkled sheets is likely to sustain tissue damage as a result of friction. The skin over the elbows and heels often is injured due to friction when patients lift and help move themselves up in bed with the use of their arms and feet. Friction burns can also occur on the back when patients are pulled or slid over sheets while being moved up in bed or transferred onto a stretcher.

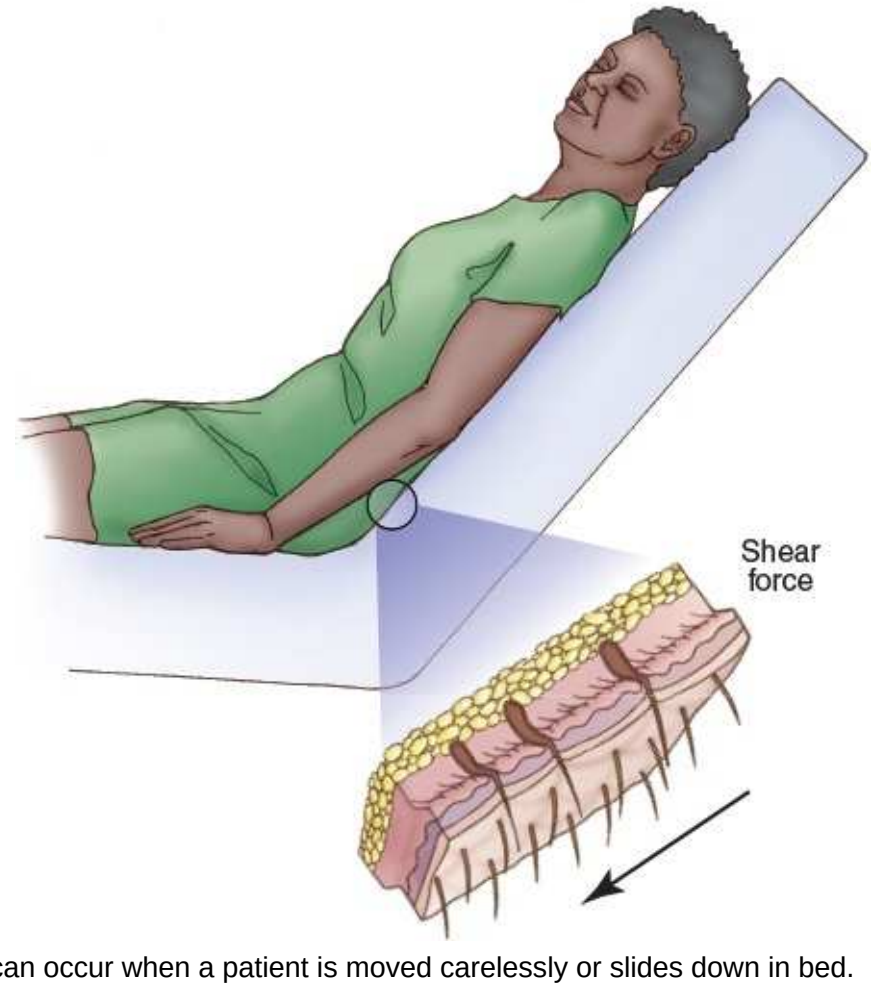

FIGURE 33-5. Shearing forces can occur when a patient is moved carelessly or slides down in bed.

Shear results when one layer of tissue slides over another layer. Shear separates the skin from underlying tissues. Shear includes shear stress, the force, and shear strain, the "distortion or deformation of tissue" (NPIAP, 2019, p. 5) secondary to shear stress. The small blood vessels and capillaries in the area are stretched and possibly tear, resulting in decreased circulation to the tissue cells under the skin. Figure 33-5 illustrates how shearing forces occur. Patients who are pulled, rather than lifted, when being moved up in bed, or from bed to chair or stretcher are at risk for injury from shearing forces. A patient who is partially sitting up in bed is susceptible to shearing force when the skin sticks to the sheet and underlying tissues move downward with the body toward the foot of the bed. This may also occur in a patient who sits in a chair but slides down.

MICROCLIMATE

Microclimate refers to the temperature and moisture (humidity) of the skin that comes into contact with a support surface, such as a bed or device (NPIAP, 2019). Skin that is moist does not have the same tolerance for pressure and shearing forces as skin that is dry (Corum, 2019). When skin is damp (from incontinence, perspiration, or drainage/exudate), it requires less friction to blister and abrade, which can lead to a pressure injury. Moisture from urinary and/or fecal incontinence has been linked to an increased likelihood of sacral pressure injury (Alvarez et al., 2016). There are four types of moisture-associated skin damage (MASD) identified in the literature: (1) incontinence-associated dermatitis (IAD) that results from chronic exposure to urine and/or stool, (2) perspiration-based (intertriginous) dermatitis (ITD), (3) periwound MASD due to exudate, and (4) peristomal MASD that occurs with ostomy output (McNichol et al., 2018).

Risks for Pressure Injury Development

In addition to pressure, friction, and shear, a combination of causes contributes to pressure injury development. These include immobility, nutrition, hydration, mental status, and age; these factors are addressed here. Additional risk factors are outlined in Box 33-3.

Box 33-3 Risk Factors for Pressure Injury Development

Mobility and activity limitations are required conditions for pressure injury development. In the absence of mobility issues, the risk factors listed here should not result in the formation of a pressure injury. Note that the development of a pressure injury may be unavoidable, even with preventative measures, in situations such as multiple organ dysfunction syndrome (MODS) where hemodynamic instability, inadequate nutrition/hydration, and immobility occur (Alvarez et al., 2016). Inadequate nutrition and dehydration, skin moisture, altered mental status, and advanced age are factors in the development of pressure injuries. In addition, patients compromised by the following conditions are at risk for pressure injury development:

- Poor skin hygiene
- Diabetes mellitus
- Diminished sensory perception (pain awareness)
- Fractures
- History of corticosteroid therapy
- General poor health
- Immobility secondary to paralysis or injury/illness
- Immunosuppression
- Incontinence—urinary or fecal
- Increased body temperature
- Microvascular dysfunction
- Multiple organ dysfunction syndrome (MODS)
- Previous pressure injuries
- Poor nutrition and hydration
- Sedation or coma
- Significant obesity or thinness
- Smoking
- Surgery
- Terminal illness/end-of-life/dying process

(2019b). *Prevention and treatment of pressure ulcers/injuries: Clinical practice guideline—The international guideline* (3rd ed.) E. Haesler (Ed.). Cambridge Media.

IMMOBILITY

Patients who spend long periods of time in bed or seated without shifting their body weight properly are at great risk for developing a pressure injury. People who are ambulatory usually do not develop this type of injury because no part of the body experiences prolonged pressure. In addition, when asleep, healthy people tend to move about in bed freely. Patients who are unconscious and paralyzed, those with cognitive impairments, those experiencing depression, or those with other physical limitations such as a fracture, are subject to pressure injuries if they are allowed to remain in any one position for an extended period. Additional factors that cause immobility and may result in this serious problem include surgery and the use of tranquilizers or sedatives.

NUTRITION AND HYDRATION

Protein–calorie malnutrition predisposes a person to pressure injury formation because poorly nourished cells are damaged easily. Protein deficiency leading to a negative nitrogen balance, electrolyte imbalances, and insufficient caloric intake also predisposes the skin to injury. Other deficiencies can increase risk. For example, vitamin C deficiency causes capillaries to become fragile, with resultant poor circulation to the area. The condition of the teeth or fit of dentures may also exacerbate the problem of inadequate dietary intake. Dehydration as well as edema can interfere with circulation and subsequent cell nourishment.

MENTAL STATUS

The more alert a person is, the more likely the person is to protect skin integrity by relieving pressure periodically and maintaining adequate skin hygiene. Apathy, confusion, or a comatose state can diminish these self-care abilities and increase the likelihood of skin breakdown.

AGE

Older adults are at a greater risk for pressure injury because the aging skin is more susceptible to injury. Chronic and debilitating diseases, more common in this age group, may adversely affect circulation and oxygenation of dermal structures. Other problems, such as malnutrition and immobility, compound the risk of pressure injury development in older adults.

Pressure Injury Staging

Although not a pressure injury, blanching (becoming pale and white) of the skin area under pressure may be an early warning sign of potential injury development. When pressure is relieved, blanching, which represents ischemia, is rapidly followed by hyperemia, a reddening in lightly pigmented skin. The body literally floods the area with blood to nourish and remove wastes from the cells. The area appears red and feels warm, but blanches when slight pressure is applied. After a patient who has been lying supine for 2 hours is repositioned onto the side, any reddened area due to reactive hyperemia should fade within 60 to 90 minutes. In patients with darkly pigmented skin, it may be best to assess for hyperemia by touch; the skin feels warm. Any potential change in color or temperature should be considered in relation to the surrounding tissue. Skin texture (taut, shiny, hardened) provides additional information for patients whose skin does not show blanching.

If the pressure is not removed when this ischemia occurs, circulation is further impaired, and a pressure injury develops. Appropriate intervention depends on early recognition of the stage of development of the pressure injury. Pressure injuries are commonly classified according to six stages (four numbered and two unnumbered): stage 1, stage 2, stage 3, stage 4, unstageable, and deep tissue pressure injury (DTPI; Edsberg et al., 2016; NPIAP, 2016a).

When assessing pressure injuries, it is important to note that this staging system should be used for pressure injuries only; it does not apply to injuries that may occur secondary to moisture (such as IAD), intertriginous dermatitis (an inflammatory condition that occurs in skin folds), injuries related to medical adhesive, neuropathic (diabetic) ulcers, vascular ulcers, mucosal membrane pressure injuries (with a history of medical device use at the location of the injury), or injuries from traumatic wounds (such as burns, tears, or abrasions; Edsberg et al., 2016; NPIAP, 2016a). A stage 1 pressure injury is a defined, localized area of intact skin with nonblanchable **erythema** (redness in lightly pigmented skin). Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding skin. The area may be painful, firm, soft, warmer, or cooler as compared to adjacent tissue (Edsberg et al., 2016; NPIAP, 2016a). A stage 2 pressure injury involves partial-thickness loss of dermis and presents as a shallow, open ulcer or a ruptured/intact serum-filled blister (Edsberg et al., 2016; NPIAP, 2016a). A stage 3 pressure injury presents with full-thickness tissue loss. Subcutaneous fat may be visible and epibole (rolled wound edges) may occur, but bone, tendon, or muscle is not exposed. Slough and/or eschar that may be present do not obscure the depth of tissue loss. Ulcers at this stage may include undermining and tunneling (Edsberg et al., 2016; NPUAP, 2016a). Stage 4 injuries involve full-thickness tissue loss with exposed or palpable bone, cartilage, ligament, tendon, fascia, or muscle. Slough or eschar may be present on some part of the wound bed; epibole, undermining, and/or tunneling often occur (Edsberg et al., 2016; NPIAP, 2016a).

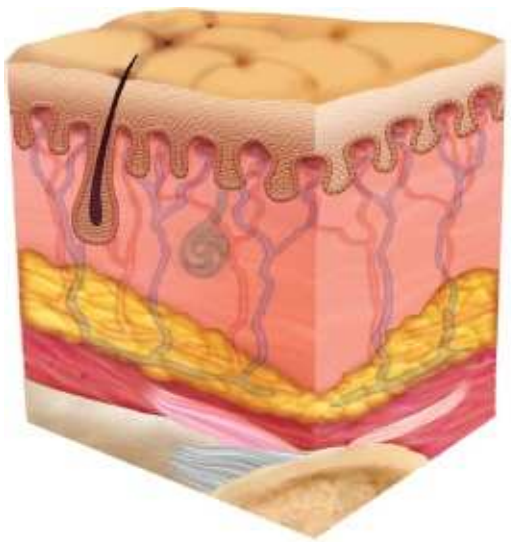
Concept Mastery Alert

The updated pressure injury staging system includes Arabic, not Roman numerals; the descriptions of the four stages (and two unstageable definitions) were formed based on a consensus of experts in 2016.

When the clinician is unable to visualize the extent of tissue damage due to slough or eschar, pressure injuries are classified as unstageable. Slough is yellow, tan, gray, green, or brown dead tissue; eschar is tan, brown, or black hardened dead tissue (necrosis) in the wound bed (EPUAP, NPIAP, & PPPIA, 2019b). Eschar and/or slough must be removed before the stage (3 or 4) can be determined. However, stable (dry, adherent, intact, without erythema or fluctuance) eschar on the heels or ischemic limb should not be removed or softened (NPIAP, 2016a).

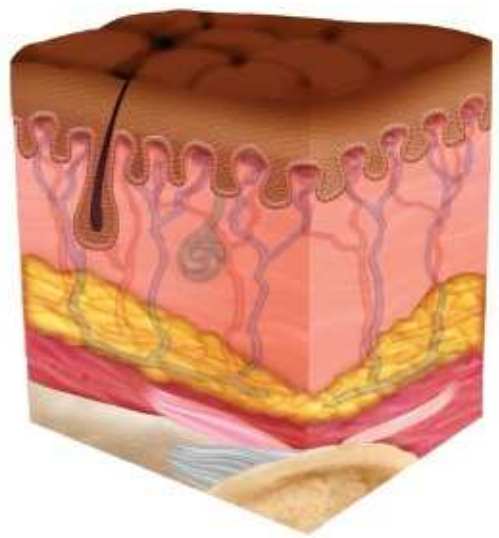
Suspected deep-tissue injury presents as a persistent, nonblanchable purple or maroon discoloration of intact or nonintact skin, or separation of the epidermis that reveals a dark wound bed or blood-filled blister (NPIAP, 2016ab). The process that results in deep tissue injury begins about 48 hours before any visible deep red, purple, or maroon skin is evident, making it difficult to be sure of the cause of injury (NPIAP, 2021). It may initially present as a painful, firm, mushy, boggy, warmer, or cooler area as compared to adjacent tissue (EPUAP, NPIAP, & PPPIA, 2019b). This type of injury typically results from intense and/or prolonged pressure and shearing where the bone and muscle interface (NPIAP, 2016a).

Detailed descriptions of these stages and a visual representation are presented in Box 33-4.



Box 33-4 **Pressure Injury Stages**

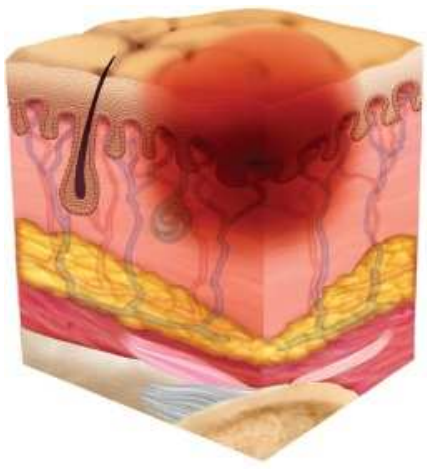
Pressure Injury



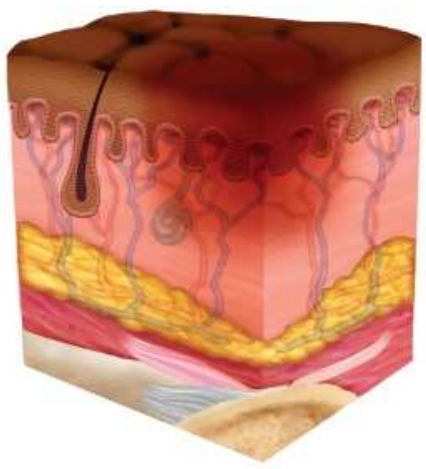
A pressure injury is localized damage to the skin and underlying soft tissue usually over a bony

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

prominence or related to a medical or other device. The injury can present as intact skin or an open ulcer and may be painful. The injury occurs as a result of intense and/or prolonged pressure or pressure in combination with shear. The tolerance of soft tissue for pressure and shear may also be affected by microclimate, nutrition, perfusion, comorbidities, and condition of the soft tissue.



Healthy skin, lightly pigmented.[a]

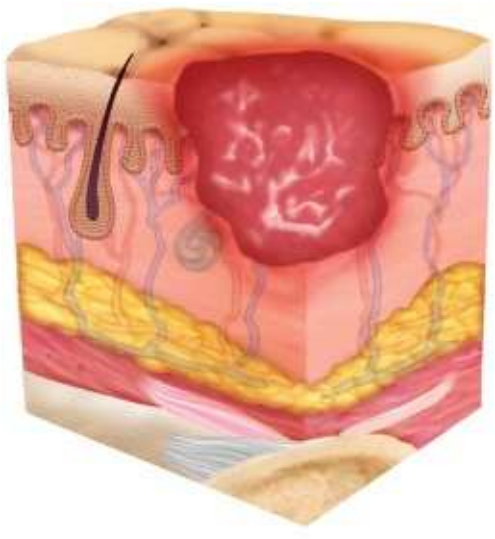


Healthy skin, darkly pigmented.[a]

Stage 1 Pressure Injury: Nonblanchable Erythema of Intact Skin

Intact skin with a localized area of nonblanchable erythema, which may appear differently in darkly pigmented skin. Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Color changes do not include purple or maroon discoloration; these may indicate deep tissue pressure injury.

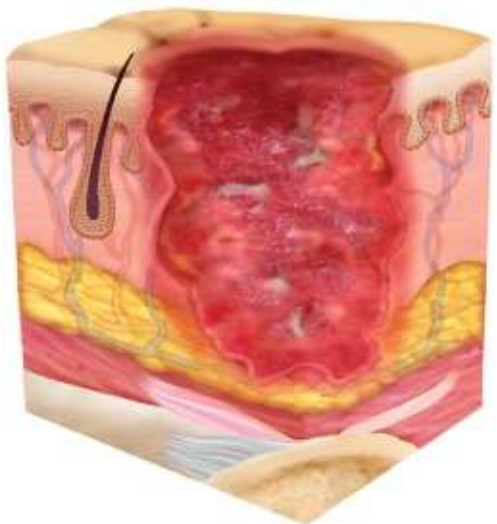
Stage 1 pressure injury, lightly pigmented.[a]



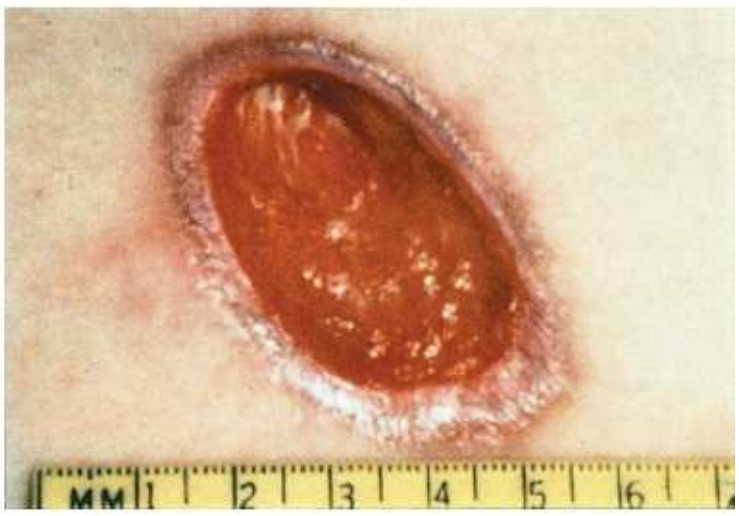
Stage 1 pressure injury, darkly pigmented.[a]

Stage 2 Pressure Injury: Partial-Thickness Skin Loss With Exposed Dermis

Partial-thickness loss of skin with exposed dermis. The wound bed is viable, pink or red, moist, and may also present as an intact or ruptured serum-filled blister. Adipose (fat) is not visible and deeper tissues are not visible. Granulation tissue, slough, and eschar are not present. These injuries commonly result from adverse microclimate and shear in the skin over the pelvis and shear in the heel. This stage should not be used to describe moisture-associated skin damage (MASD) including incontinence-associated dermatitis (IAD), intertriginous dermatitis (ITD), medical adhesive–related skin injury (MARSI), or traumatic wounds (skin tears, burns, abrasions).



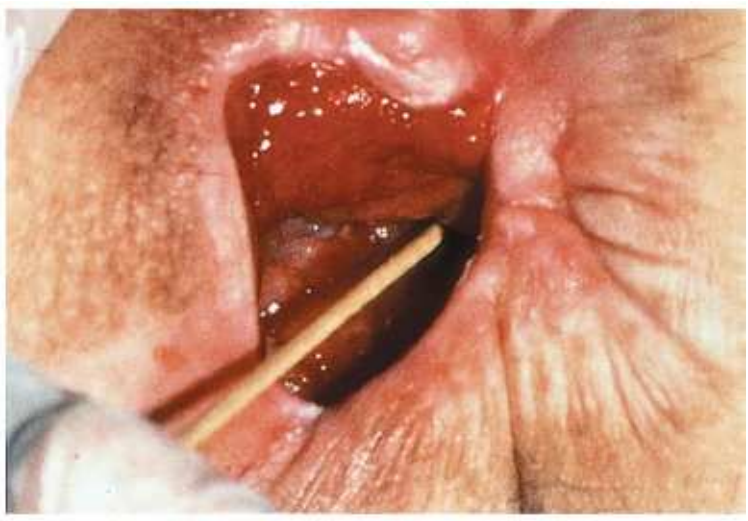
Stage 2 pressure injury.[a]



Stage 3 Pressure Injury: Full-Thickness Skin Loss

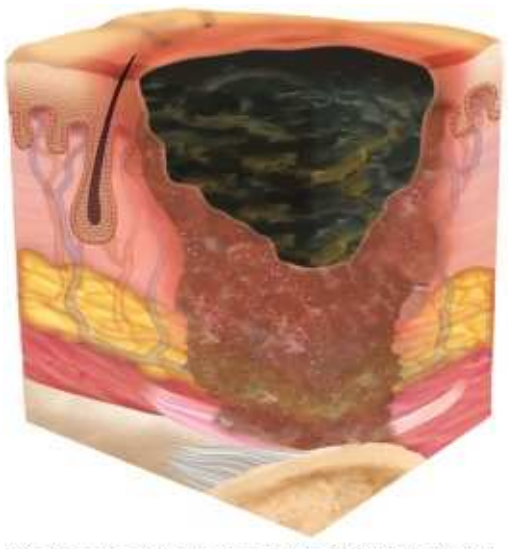
Full-thickness loss of skin, in which adipose (fat) is visible in the ulcer and granulation tissue and epibole (rolled wound edges) are often present. Slough and/or eschar may be visible. The depth of tissue damage varies by anatomical location; areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, and/or bone are not exposed. If slough or eschar obscures the extent of tissue loss, this is an Unstageable Pressure Injury.

Stage 3 pressure injury.[a]

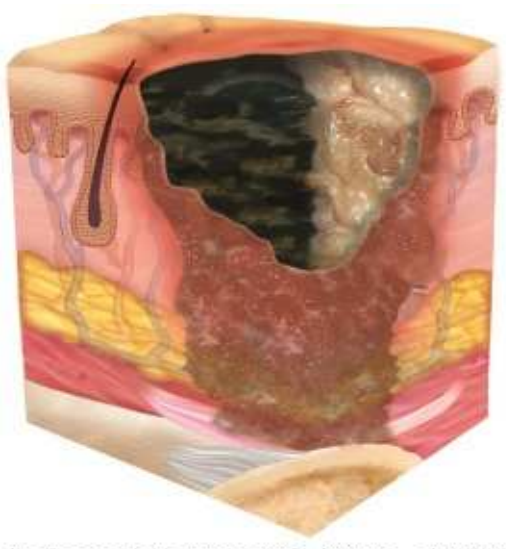


Stage 4 Pressure Injury: Full-Thickness Skin and Tissue Loss

Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage or bone in the ulcer. Slough and/or eschar may be visible. Epibole (rolled edges), undermining, and/or tunneling often occur. Depth varies by anatomical location. If slough or eschar obscures the extent of tissue loss, this is an Unstageable Pressure Injury.



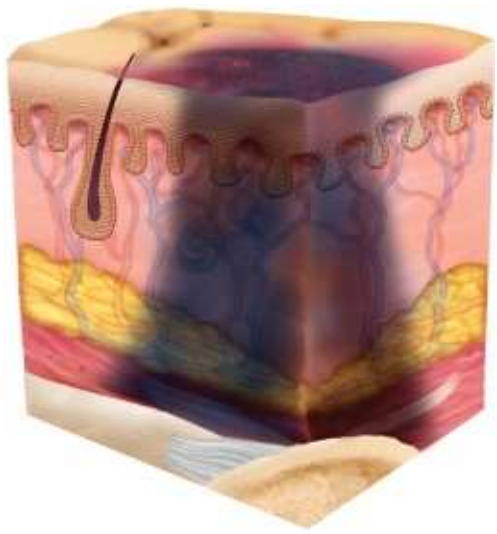
Stage 4 pressure injury.[a]



Unstageable Pressure Injury: Obscured Full-Thickness Skin and Tissue Loss

Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough or eschar is removed, a stage 3 or stage 4 pressure injury will be revealed. Stable eschar (i.e., dry, adherent, intact without erythema or fluctuance) on the heel or ischemic limb should not be softened or removed.

Unstageable pressure injury, dark eschar.[a]



Unstageable pressure injury, slough and eschar.[a]

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Deep Tissue Pressure Injury: Persistent Nonblanchable Deep Red, Maroon, or Purple Discoloration

Intact or nonintact skin with localized area of persistent nonblanchable deep red, maroon, or purple discoloration or epidermal separation revealing a dark wound bed or blood-filled blister. The process leading to deep tissue pressure injury (DTPI) begins 48 hours prior to any color changes. Pain and temperature change often precede skin color changes. Discoloration may appear differently in darkly pigmented skin. This injury results from intense and/or prolonged pressure and shear forces at the bone–muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury, or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle, or other underlying structures are visible, this indicates a full-thickness pressure injury (unstageable, stage 3, or stage 4). Do not use DTPI to describe vascular, traumatic, neuropathic, or dermatologic conditions.

Deep tissue pressure injury.[a]

Psychological Effects of Wounds and Pressure Injuries

Because the skin is a sensory organ and plays a major role in communication with others and self-image, wounds and pressure injuries require emotional as well as physical adaptation. Although stress and adaptation vary greatly among people, actual and potential emotional stressors are common in all patients with wounds. These stressors impact the quality of life of the patient and caregivers and include pain, anxiety, fear, activities of daily living, and changes in body image.

Pain

Pain is part of almost any trauma, from a small cut on the finger, to a chronic arterial ulcer or large incision made during abdominal surgery. Although pain can be considered a physical complication, it also has a large psychological component. Pain from wounds is often increased by activities such as ambulating, coughing, moving in bed, and dressing changes. The actual pain might be worsened by the patient's apprehension about such activities. Nursing interventions to reduce pain can greatly reduce emotional stress. See Chapter 36 for a more in-depth discussion of pain.

Anxiety and Fear

Anxiety and fear are common responses to a wound. Patients are apprehensive about the possibility of the wound opening, how much privacy will be lost as the wound is being cared for, and how they and others will react to the appearance and smell of the wound. When caring for patients with wounds, demonstrating acceptance and empathy, encouraging the expression of feelings, answering questions accurately and honestly, and avoiding excessive exposure of body parts when providing wound care are essential.

Activities of Daily Living

The presence of an acute or chronic wound or pressure injury can impact the ability of an individual to perform activities of daily living. Physical, financial, and medical restrictions can result in limitations on a person's ability to perform daily activities. The inability to perform any activity related to self-care (such as feeding oneself, bathing, dressing, grooming), work, homemaking, or leisure activities can negatively impact the person's quality of life.

Changes in Body Image

Body image reflects a person's view of oneself as a whole entity. When the skin and tissues are traumatized, that image is changed, requiring the person to adapt and reformulate their concept of self. Wounds and scars that are visible to others, especially on the face, can result in feelings of conspicuousness, ugliness, and diminished self-worth. Large scars, such as from removal of a breast or from creation of a colostomy opening, can seriously affect the person's sexuality, social relationships, and self-concept. Referral to support groups or counselors may be necessary to facilitate coping and acceptance of changes in body structure or function. See the Focused Critical Thinking Guide 33-1 on page 1168. In addition, Chapter 42 contains more information about self-concept.

NURSING PROCESS FOR WOUNDS AND PRESSURE INJURIES

Assessing

The patient's health history is an essential component for assessing the patient's integumentary status and identification of risk factors for problems with the skin. This information can be obtained from either the patient or a person identified by the patient. The nursing examination combined with laboratory findings can provide information to identify a patient's strengths, as well as the nature of any problems, their course, related signs and symptoms, onset, frequency, and their effects on activities of daily living. The nurse decides, based on these findings, what problems can be treated independently by nursing. Other problems are referred to other members of the interprofessional team for decisions on treatment.

33-1 Focused Critical Thinking Guide

Wound Care: Promoting Acceptance of Changes in Body Image

During both clinical days in 1 week, you have been assigned to care for a middle-aged woman who has had a breast removed because of cancer. The patient, Mrs. Nola, is an attractive, usually cheerful woman who is eager to get better and return home. However, on both days, she turned her head away and would not look at the incision when her dressing was changed. She tells you that she "just can't stand to look at herself." Her husband has left the room during the dressing changes after telling you that "it makes me sick to see what happened to my wife." Mrs. Nola is to be discharged to her home the next day and needs to learn how to provide self-care for her wound. What do you do?

1. Identify goal of thinking

Determine the most effective way of ensuring wound care while also assisting Mrs. Nola in accepting her altered self-image.

2. Assess adequacy of knowledge

Pertinent circumstances: The diagnosis of cancer was made only 2 weeks before the surgical removal of the breast. The patient is to be discharged to her home the next day. The wound from her mastectomy has not completely healed and will require dressing changes for another 3 or 4 days. Mrs. Nola has had a disfiguring surgery and is coping with not only a change in body image, but also the diagnosis of cancer. She has never been seriously ill or had surgery. She has a strong, loving relationship with her husband, but he is unable to deal with the physical disfigurement at this time.

Prerequisite knowledge: Before you decide what to do in this situation, you need to know how Mrs. Nola is coping with her diagnosis of cancer. If she is still in denial about the disease, it is likely that she is also denying the surgical procedure and the changes in her body. You will need to review responses to the diagnosis of cancer as well as the stages of grief and loss. You will have to learn what her sources of support are and how she can best access and use them. You will need to assess how best to help her achieve wound care in the face of her continued refusal even to look at the wound.

Room for error: If she is forced to look at the wound or made to feel inadequate because of her inability to do so, she may feel threatened and may become angry in response to the perceived threat and retreat even further.

Time constraints: Some decision about wound care must be made before her discharge the next day.

3. Address potential problems

There are several potential obstacles to critical thinking in this situation. As a student, you want to exhibit safe, knowledgeable care, and the importance of teaching for home care has been an emphasis in this course. You have a sense of what the loss of a breast must mean, but know you cannot truly understand her lived experience. Having had a family member die of cancer, you find yourself wanting to do everything for Mrs. Nola. As a novice in nursing, you find it difficult to handle these emotional components of patient care and find yourself wanting to focus objectively on the task at hand and scold both the patient and her husband for being so silly about something

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

as simple as a dressing change.

4. Consult helpful resources

You must first appreciate the loss and grief Mrs. Nola is experiencing, and you must then relate that to her response to self-care of the wound. Your best source of information about her coping methods and sources of personal strength is Mrs. Nola herself. You also discuss the most effective way of providing wound care at home with your instructor and the case manager for Mrs. Nola.

5. Critique judgment/decision

After talking to Mrs. Nola, your instructor, and the case manager, you mutually agree that Mrs. Nola cannot be hurried into acceptance of her medical diagnosis or her body changes. The case manager consults with Mrs. Nola's provider, who writes a prescription for a home health care nurse to visit for the next 4 days and complete the dressing change. After talking with Mrs. Nola, you identify that she is still very much in denial. You discuss with her the possibility of having a visitor from "Reach to Recovery," a support group for women with breast cancer who have had a mastectomy. Mrs. Nola tells you that she thinks she would like to talk to someone with the same diagnosis, and you call a referral for her. When you tell Mrs. Nola that a home health care nurse will be visiting her for the first few days at home to change her dressing and ensure Mrs. Nola can appropriately change the dressing herself, tears fill her eyes. She says, "I am so scared—I just don't know what to do." You realize that insisting that Mrs. Nola do her own dressing (in this moment) would have been extremely stressful for her. Focusing solely on the task would have been perceived as dismissive and could have negatively impacted on the trusting relationship you were trying to form with the patient. When you share the situation in postconference, your clinical group supports your clinical judgment.

Focused Assessment Guide 33-1

SKIN INTEGRITY

Factors to Assess	Questions and Approaches
Appearance of skin	• Do you have any skin areas that are discolored from your baseline coloration? Any gray (ashy) patches on your arms, elbows, lower legs, knees, or heels? • Have you noticed any texture changes in your skin? Bumps? Rough patches? Cracked thin lines? • Do some areas of skin on your body feel warmer or colder than others? • Describe the moisture in your skin: is it damp, dry, oily? • Have you noticed that your skin seems to be thinner? Where? • Have you noticed any swelling in your feet, ankles, or fingers? • Tell me about how you take care of your skin. For example, do you take a tub bath or shower? How often? Do you regularly use oils or lotions?
Recent changes in skin	• Do you have any sores on your body? If so, how many, and where are they? Have they changed in size? Do you have any drainage from them? • Have you noticed that the skin over your hips or backbone gets red/discolored if you sit or lie in one position for a long time? Any associated temperature changes in the skin? Does this disappear in a short time when you are up? • Have you gotten a piercing or tattoo recently? • Any recent surgical incisions or existing scars?
Activity/mobility	• Do you need assistance to walk or move? If so, how much? • Are you confined to your bed or a chair? • Can you independently change your position when you want to?
Nutrition	• Have you gained or lost weight recently? • Describe your usual meals each day. • How many glasses or cups of liquid do you drink each day? • Do you take any food supplements or vitamins? • Do you prepare your own meals? • Do you wear dentures? How do they fit? • Do you have any difficulty chewing or swallowing? • Has a doctor ever told you that you are anemic?
Pain	• If you have a sore, is it painful? • Do you take anything for pain? If so, what do you take, and how often? Does it help?
Elimination	• Have you noticed any problems (frequency, color, consistency, odor) with your bowels or urination? If so, describe. • Have you ever used pads or special pants because you can't control your urine or stools?

Nursing History

When obtaining the nursing history, include questions about the appearance of the skin and patient activities that may contribute to the development of a pressure injury. Often a combination of factors places the patient at greatest risk for a pressure injury.

Question the patient and family about recent changes in the appearance or condition of the skin and any skin care

regimens. Also, assess activity status, nutritional state, elimination patterns, and cognitive state.

Evaluate the patient's general condition and laboratory test results. Be alert for signs and symptoms of infection, which may cause generalized malaise, increased pain, anorexia, and an elevated body temperature and pulse rate. Laboratory data indicating an infection include an elevated WBC count and, if a wound culture has been done, identification of a causative organism.

The accompanying Focused Assessment Guide 33-1 provides additional suggestions for gathering a nursing history.

Skin Assessment

Skin assessment should be an integral part of every patient's care. Physical assessment of the skin is included as part of the initial database collection. Skin assessment provides needed information for developing an appropriate plan of care. The inspection and palpation skills used to assess the integumentary system are described in detail in Chapter 27. Be sure to inspect the skin systematically in a head-to-toe fashion, including bony prominences, on admission and then at regular intervals for all at-risk patients. Reassessment is recommended (NPIAP, 2020), as follows:

- *Acute care setting:* On admission, then reassess every shift and with any change in condition
- *Long-term care setting:* On admission, then reassess weekly for 4 weeks, then quarterly and whenever the resident's condition changes
- *Home health care:* On admission, then reassess at every visit

Early detection and treatment of skin problems are important nursing functions. It is important to provide patients with a proactive strategy for skin care. Many conditions and wounds, particularly pressure injuries, can be prevented or minimized with early intervention. Interventions to promote skin health are discussed in Chapter 32.

Wound Assessment

Wound assessment involves inspection (sight and smell) and palpation for appearance, drainage, odor, and pain. Wound assessment determines the status of the wound, identifies barriers to the healing process, and identifies signs of complications. Accurate assessment provides essential baseline data and information to judge the effectiveness of treatment and wound healing progression. Skin integrity and wound assessment are performed at regular intervals, based on the nature of the wound and facility policy.

APPEARANCE OF THE WOUND

Note the location of the wound. Location is described in relation to the nearest anatomic landmark, such as bony prominences. Document the size of the wound. Measurements are taken in millimeters or centimeters, measuring length, width, and depth. Refer to Guidelines for Nursing Care 33-1 for details on measuring a wound.

▶ Guidelines for Nursing Care 33-1

Measuring Wounds and Pressure Injuries

Size of the Wound

- Draw the shape and describe it.
- Using agency protocol, measure the head-to-toe length, side-to-side width, and depth—use the greatest measurement for length, width, and depth.

Depth of the Wound

FIGURE A

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE B

- Perform hand hygiene. Put on gloves.
- Moisten a sterile, flexible, cotton-tipped applicator with saline and insert it gently into the wound at a 90-degree angle with the tip down (Figure A).
- Mark the point on the swab that is even with the surrounding skin surface or grasp the applicator with the thumb and forefinger at the point corresponding to the wound's margin (Figure B).
- Remove the swab and measure the depth with a ruler (Figure C).

Wound Tunneling

- Use standard precautions; use appropriate transmission-based precautions when indicated.

  - Perform hand hygiene. Put on gloves.
  - Determine direction: Moisten a sterile, flexible, cotton-tipped applicator with saline and gently insert a sterile applicator into the site where tunneling occurs. View the direction of the applicator as if it were the hand of a clock (Figure D). The direction of the patient's head represents 12 o'clock. Moving in a clockwise direction, document the deepest sites where the wound tunnels.
- Determine the depth: While the applicator is inserted into the tunneling, mark the point on the swab that is even with the wound's edge or grasp the applicator with the thumb and forefinger at the point corresponding to the wound's margin. Remove the swab and measure the depth with a ruler (see Figure C).
- Document both the direction and depth of tunneling.

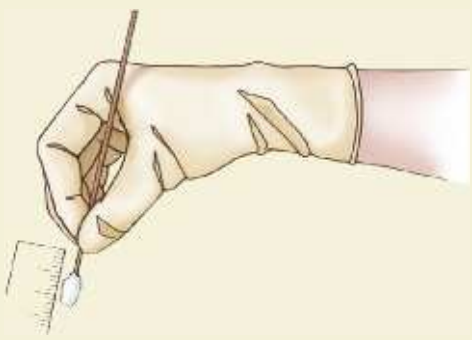

FIGURE C

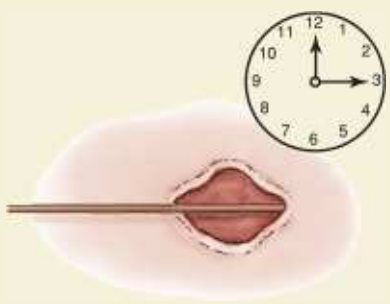

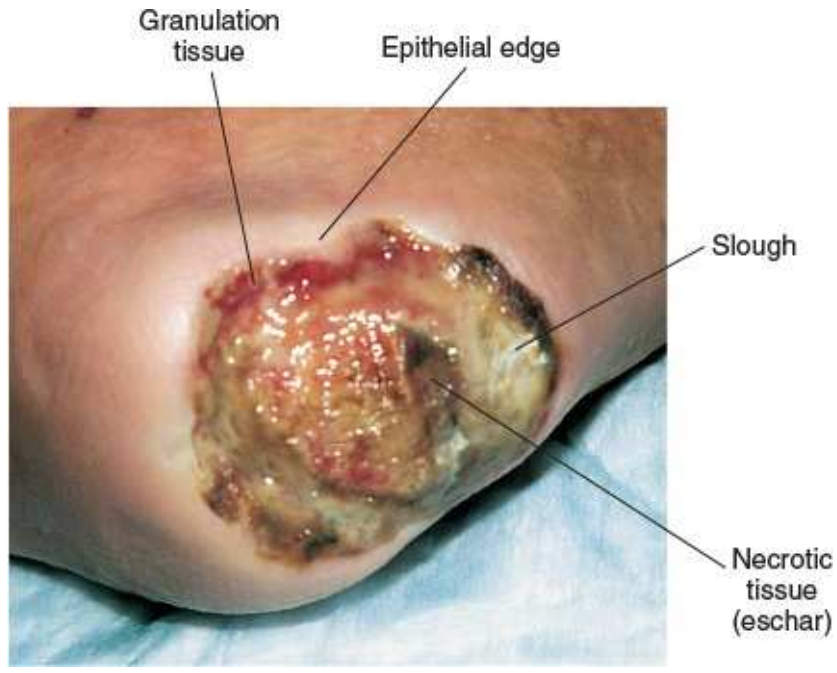

FIGURE D

Box 33-5 **RYB Wound Classification**

A color classification system termed RYB (red-yellow-black) can be used for wound assessment and to help direct treatment for open wounds, or healing by secondary intention (Hess, 2019; Krasner, 1995; Stotts, 1990). This classification, with related interventions, is based on the assessment of wound color. However, many wounds have red, yellow, and black components and are categorized as mixed wounds (see Figure). When all colors are present, the wound is treated first for the most serious color: black, followed by yellow, and finally red.

R = Red = Protect

Red wounds are in the proliferative stage of healing and reflect the color of normal granulation tissue. Wounds in this stage need protection with nursing interventions that include gentle cleansing, use of moist dressings, and changing of the dressing only when necessary, and/or based on product manufacturer's recommendations.

Y = Yellow = Cleanse

Yellow in the wound may indicate the presence of exudate (drainage) or slough and requires wound cleaning. These wounds are characterized by oozing from the tissue covering the wound, often accompanied by purulent drainage. Drainage can be whitish yellow, creamy yellow, yellowish green, or beige. To cleanse these wounds, nursing interventions include the use of wound cleansers and irrigating the wound.

B = Black = Debride

Black in the wound may indicate the presence of an eschar (necrotic tissue), which is usually black but may also be brown, gray, or tan. The eschar requires debridement (removal) before the wound can heal. These wounds are often cared for by advanced practice nurses who are educated in the care of more complex wounds. After debridement, the wound is treated as a yellow wound and then, as healing progresses, a red wound.

Assess wounds for the approximation of the wound edges (edges meet) and signs of dehiscence or evisceration. Assess the color of the wound and surrounding area. Note the presence of drains, tubes, staples, and sutures. The edges of a healthy healing surgical wound appear clean and well approximated, with a crust along the wound edges. Initially, the edges are reddened and slightly swollen. After approximately 1 week, the skin is closer to normal in appearance, with wound edges healing together. The skin surrounding the wound may at first be bruised, but this too returns to normal as blood is reabsorbed.

When infection is present, the wound is swollen and deep red. It feels hot on palpation, and drainage is increased and possibly purulent. If dehiscence is impending or present, the wound edges are separated. If the wound edges have separated and the wound is open, describe the type of tissue in the wound: granulation, slough, or eschar (see Box 33-5).

Assess for the presence of odor, but only after the wound has been cleaned. The presence of odor can be indicative of certain types of bacteria.

DRAINAGE

The inflammatory response results in the formation of exudate which then drains from the wound. The exudate may contain fluid/serum, cellular debris, bacteria, and leukocytes (Baranoski & Ayello, 2020). This exudate is called wound drainage and is described as serous, sanguineous, serosanguineous, or, if infected, purulent.

- **Serous drainage** is composed primarily of the clear, serous portion of the blood and from serous membranes. Serous drainage is clear and watery.
- **Sanguineous drainage** consists of large numbers of red blood cells and looks like blood. Bright-red sanguineous drainage is indicative of fresh bleeding, whereas darker drainage indicates older bleeding.
- **Serosanguineous drainage** is a mixture of serum and red blood cells. It is light pink to blood tinged.
- **Purulent drainage** is made up of white blood cells, liquefied dead tissue debris, and both dead and live bacteria. Purulent drainage is thick, often has a musty or foul odor, and varies in color (such as dark yellow or green),

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

depending on the causative organism.

Drains may be inserted in or near a wound to promote drainage, reducing the risk of abscess formation and promoting wound healing. Various types of drains are described in Table 33-4 on page 1172 and discussed later in this chapter.

Assess the amount, color, odor, and consistency of wound drainage. The amount and color depend on the wound location and size. Generally speaking, a small amount of exudate covers less than one third of the dressing, a moderate amount covers one third to two thirds of the dressing, and a large amount covers more than two thirds of the dressing (Baranoski & Ayello, 2020). Typically, larger wounds have more drainage than smaller wounds. Assess wound drainage on the wound, on the dressings, in drainage bottles or reservoirs, or—depending on the location of the wound and the amount of drainage—under the patient.

Table 33-4 Common Types of Drains

TYPE: OPEN	PURPOSE	EXAMPLE
Gauze, iodoform gauze, NuGauze—gauze dressings packed loosely so the wound is allowed to drain	Allow healing from base of wound	Infected wounds, after removal of hemorrhoids
Penrose: open drainage system consisting of a soft rubber tube that provides a sinus tract	Drains blood and fluid	After incision and drainage of abscess, in abdominal surgery
TYPE: CLOSED	**PURPOSE**	**EXAMPLE**
Blake: silicon tube with four chambers—similar to a JP externally	Drains blood and fluid	Used in cardiac surgery in place of a chest tube or JP drain
Chest tube: mediastinal placement (different from a chest tube used in the pleural space)	Drains blood	After cardiac surgery
Hemovac: portable negative pressure suction device	Drains blood and fluid	After abdominal, orthopedic surgery
Jackson-Pratt (JP): bulb suction device	Drains blood and fluid	After breast surgery or mastectomy, abdominal surgery
T-tube: T-shaped tube placed in the common bile duct	Collects bile	After gallbladder surgery

SUTURES AND STAPLES

Skin sutures are used to hold tissue and skin together. Sutures may be silk, synthetic material, or fine wire, and are classified as absorbable or nonabsorbable. Nonabsorbable sutures are removed when enough tensile strength has developed to hold the wound edges together during healing. The time frame varies depending on the patient's age, nutritional status, and wound location. Frequently, after skin sutures are removed, small wound-closure strips of adhesive are applied across the wound to give additional support as it continues to heal. New developments in sutures include drug-eluting (slow release) sutures, stem cell seeded sutures, antimicrobial sutures, and even elastic and electronic sutures (Dennis et al., 2016). Figure 33-6 shows an example of an incision with sutures. Retention sutures are used to provide extra support for patients with obesity and for wounds with an increased risk for dehiscence. The use of staples to close the skin may reduce the time required in the operating room, but there is some indication that the use of sutures may slightly reduce pain postoperatively, adverse events, and readmission rates. More research needs to be done on this topic (Cochetti et al., 2020).

FIGURE 33-6. Incision with sutures.

Chronic Wound Assessment

Chronic wounds are often related to vascular or circulatory issues, with the lower extremities being the most frequently affected. Wound assessment of chronic wounds must address the unique components of these wounds and incorporate evidence-based practices that promote wound healing. The ABCESS acronym that was originally developed for students in podiatric medicine, provides an assessment framework that can be applied to chronic wounds of the lower extremity (McGuire et al., 2020):

- A: **A**ll of the patient—history, physical, and overview of patient status
- B: Wound **b**ed management—**b**ioload, **b**iofilm, **b**iomarkers, and **b**iopsy
- C: **C**irculation—arterial, venous, and lymphatic
- E: **E**dema, **e**xudate, and **e**rythema management—including dressing and compression
- S: **S**kin protection and treatment
- S: **S**ocial, **s**ocietal, and **s**piritual factors

Pressure Injury Assessment

It is a nursing priority to perform a comprehensive assessment in all settings. Nurses need to identify patients at risk for pressure injuries due to predisposing factors and recognize when there is evidence of actual pressure injuries.

RISK ASSESSMENT

Although no one risk assessment tool is universally recommended, these tools are part of an assessment that must be structured, comprehensive, and based on clinical judgment (EPUAP, NPIAP, & PPPIA, 2019b). A risk assessment form should be simple to use, reliable, cost effective, and supported by institutional policy (as applicable). Several scales are available to assess risk:

- Braden Scale: mental status, continence, mobility, activity, and nutrition (Braden & Maklebust, 2005; Fig. 33-7)

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Sensory Perception: Ability to respond meaningfully to pressure-related discomfort — SCORE

1. **Completely Limited:** Unresponsive (does not moan, flinch, or grasp) to painful stimuli, due to diminished level of consciousness or sedation, OR limited ability to feel pain over most of body surface.
2. **Very Limited:** Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness, OR has a sensory impairment which limits the ability to feel pain or discomfort over half of body.
3. **Slightly Limited:** Responds to verbal commands but cannot always communicate discomfort or need to be turned, OR has some sensory impairment which limits ability to feel pain or discomfort in 1 or 2 extremities.
4. **No Impairment:** Responds to verbal commands. Has no sensory deficit which would limit ability to feel or voice pain or discomfort.

Moisture: Degree to which skin is exposed to moisture — SCORE

1. **Constantly Moist:** Skin is kept moist almost constantly by perspiration, urine, etc. Dampness is detected every time patient is moved or turned.
2. **Very Moist:** Skin is often but not always moist. Linen must be changed at least once a shift.
3. **Occasionally Moist:** Skin is occasionally moist, requiring an extra linen change approximately once a day.
4. **Rarely Moist:** Skin is usually dry: linen requires changing only at routine intervals.

Activity: Degree of physical activity — SCORE

1. **Bedfast:** Confined to bed.
2. **Chairfast:** Ability to walk severely limited or non-existent. Cannot bear own weight and/or must be assisted into chair or wheelchair.
3. **Walks Occasionally:** Walks occasionally during the day, but for very short distances, with or without assistance. Spends majority of each shift in bed or chair.
4. **Walks Frequently:** Walks outside the room at least twice and inside room at least once every 2 hours during waking hours.

Mobility: Ability to change and control body position — SCORE

1. **Completely immobile:** Does not make even slight changes in body or extremity position without assistance.
2. **Very Limited:** Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently.
3. **Slightly Limited:** Makes frequent though slight changes in body or extremity position independently.
4. **No Limitation:** Makes major and frequent changes in position without assistance.

Nutrition: Usual food intake pattern — SCORE

1. **Very Poor:** Never eats a complete meal. Rarely eats more than 1/3 of food offered. Eats 2 servings or less of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement, OR is NPO and/or maintained on clear liquids or IV for more than five days.
2. **Probably Inadequate:** Rarely eats a complete meal and generally eats only about half of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally will take a dietary supplement, OR receives less than optimum amount of liquid diet or tube feeding.
3. **Adequate:** Eats over half of most meals. Eats a total of 4 servings of protein (meat, dairy products) each day. Occasionally will refuse a meal, but will usually take a supplement if offered, OR is on a tube feeding or TPN regimen, which probably meets most of nutritional needs.
4. **Excellent:** Eats most of every meal. Never refuses a meal. Usually eats a total of 4 or more servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation.

Friction and Shear — SCORE

1. **Problem:** Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures, or agitation leads to almost constant friction.
2. **Potential Problem:** Moves feebly or requires minimum assistance. During a move skin probably slides to some extent against sheets, chair, restraints, or other devices. Maintains relatively good position in chair or bed most of the time but occasionally slides down.
3. **No Apparent Problem:** Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair at all times.

3 or 4 = Moderate to Low Impairment
Total Points Possible: 23
Risk Predicting Score: 16 or Less

Risk Level
19-23 Not at risk
15-18 low risk
13-14 moderate risk
10-12 high risk
≤ 9 very high risk

NPO: Nothing by Mouth
IV: Intravenously
TPN: Total parenteral nutrition

Total Score:

- Norton Scale: physical and mental conditions, activity, mobility, and incontinence (Norton, McLaren, & Exton-Smith, 1962/1975)
- Waterlow Scale: age and gender [sex], build and weight, continence, skin type, mobility, nutrition, and special population-specific risks (Waterlow, 1985)
- Jackson/Cubbin Pressure Area Risk Calculator: age, weight and tissue viability, medical history, general skin condition, mental status, mobility, hemodynamic status, respiratory status including oxygen requirements, incontinence, and hygiene—used primarily in the intensive care unit (Jackson, 1999); see the Research in Nursing box on page 1174

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Reducing the Incidence of Hospital-Acquired Pressure Injuries

Pressure injuries are costly in terms of patient discomfort, disfigurement, decreased quality of life, fatalities, and health care expenditures. Nurses play an important role in the prevention of pressure injuries. Pressure injury prevention for patients in the critical care environment poses unique challenges.

Related Research

Higgins, J., Casey, S., Taylor, E., Wilson, R., & Halcomb, P. (2020). Comparing the Braden and Jackson/Cubbin Pressure Injury Risk Scales in trauma-surgery ICU patients. *Critical Care Nurse*, *40*(6), 52–61. https://doi.org/10.4037/ccn2020874

The purpose of this retrospective review of 366 medical records and associated analysis was to compare the predictive properties of the Braden and Jackson/Cubbin scales in critically ill patients from a trauma-surgical intensive care unit (ICU). Adult patients who were admitted to a trauma-surgical ICU, had an ICU stay of at least 72 hours, and did not have a preexisting pressure injury were included in the study. Irrespective of defined risk for pressure injury, all patients in the ICUs received interventions associated with a standard pressure injury prevention bundle. Although the Braden scale is widely used and provides efficacious predictive information, the critically ill patient demonstrates a higher propensity for oxygenation and perfusion issues, which are captured in the Jackson/Cubbin scale.

Those in the study who developed a pressure injury were older ($p = .05$), more often required vasopressors (to maintain blood pressure; $p < .001$) and mechanical ventilation (to support ventilation and oxygenation; $p < .001$), experienced incontinence ($p < .001$), and required assistance or were fully dependent for hygiene ($p < .001$). In general, the Braden scale was found to overpredict pressure injury risk, which impacts on resources and interventions, and can result in desensitization of the clinical staff. For this particular population, the Jackson/Cubbin scale outperformed the Braden scale in negative and positive predictive value, sensitivity, and specificity.

Relevance to Nursing Practice

The limitations of this study include the retrospective nature of data collection, the data collection time frame of 72 to 96 hours, the sampling strategy, and the use of one site for data collection. Although more research needs to be done to determine the best scale for determining pressure injury risk in specific populations, the clinical team associated with these trauma-surgical ICUs recommends the use of the Jackson/Cubbin scale to predict pressure injury risk.

With these tools, a numeric score is assigned to each assessment area. The degree of risk is based on the patient's total score. Using the Braden scale, a score of 19 to 23 indicates no risk; 15 to 18, mild risk; 13 to 14, moderate risk; 10 to 12, high risk; and 9 or lower, very high risk (Braden & Maklebust, 2005). Patients may have additional risk factors and/or other health problems not measured by the chosen assessment scale. Therefore, good nursing judgment may reveal the need for a higher intensity of preventive intervention than what may be identified by the scale alone (Baranoski & Ayello, 2020; Braden, 2012; Jackson, 1999).

Once a patient's risk has been identified, facilities use different approaches. Appropriate interventions are initiated based on the patient's identified risk. Many health care facilities use a pressure injury assessment form embedded in the electronic medical record that allows for trending. Documenting assessments is essential to maintaining a streamlined plan and ensuring continuity of care. All caregivers in the home or health care facility need to be aware of specific assessments, including assessment of mobility, nutritional status, and moisture and incontinence.

MOBILITY

Assessing a patient's mobility includes evaluating the patient's ability to move, turn, and reposition the body. A patient who is confined to bed or a chair or has limited range of motion is at increased risk for a pressure injury. This assessment of activity status is done upon admission to the health care facility or during the initial home care interview. The use of any assistive devices to maintain mobility and activity is noted. Additional suggestions for gathering information about mobility are described in Chapter 34.

NUTRITIONAL STATUS

The importance of sound nutrition in the prevention and treatment of a pressure injury is well established. Older adults, in particular, need adequate nutrition for optimal health and wound healing. Nutritional assessment is described in Chapter 37. Hydration and weight are important to consider, especially when unintended weight loss reaches 5% in 30 days or 10% over 180 days (Baranoski & Ayello, 2020). The following laboratory criteria that focus on diabetes and inflammatory markers (American Diabetes Association, 2022; Evans et al., 2022) indicate that a patient is nutritionally at risk for development of a pressure injury:

- Albumin level <3.2 mg/dL (normal, 3.4 to 5.4 g/dL)

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Prealbumin <15 mg/dL (normal 15 to 36 mg/dL)
- Total lymphocyte count <1,000/mm³ (normal, 1,000 to 4,800/mm³)
- Hemoglobin A1c >6.5% (normal <5.7%)
- Glucose >126 mg/dL (fasting normal <100 mg/dL)

MOISTURE AND INCONTINENCE

Many studies have documented that moisture makes the skin more susceptible to injury. Whether the moisture is from perspiration, wound drainage, urine, or stool, the skin is compromised. Moisture can create an environment in which microorganisms can multiply and the skin is more likely to blister, suffer abrasions, and become macerated. Chapters 38 and 39 have additional assessment information related to incontinence.

Remember **Mary Biesicker**, the woman who has been cared for at home by her daughter since being hospitalized last year for a cerebrovascular accident (stroke). Based on her daughter's report of Mary's increase in incontinence episodes and decreased level of functional independence, it is very likely that Mary developed a pressure injury. Keep Mary in mind as we move to explore prevention and treatment options for pressure injuries.

APPEARANCE OF EXISTING PRESSURE INJURY

Skin assessment for a pressure injury specifically includes inspection of the following (Baranoski & Ayello, 2020; NPIAP, 2020):

- Location of any lesion or ulcer
- Identification of the stage (see Box 33-4 on pages 1165–1167)
- Size of the ulcer: length, width, depth (see Guidelines for Nursing Care 33-1 on page 1170); presence of undermining, a hollow between the skin surface and the wound bed, resulting from death of the underlying tissue
- Color and type of wound tissue
- Presence of any abnormal pathways in the wound, such as a **sinus tract** (a cavity or channel underneath the wound that has the potential for infection) or *tunneling* (a passageway or opening that may be visible at skin level, but with most of the tunnel under the surface of the skin). See Guidelines for Nursing Care 33-1 on page 1170.
- Visible necrotic tissue; necrotic tissue that is in the process of separating from viable portions of the body is referred to as *slough*
- Presence of an exudate or drainage (amount and type)
- Presence of odor
- Presence or absence of granulation tissue
- Visible evidence of epithelialization
- Periwound skin condition

The Pressure Ulcer Scale for Healing (PUSH Tool) was developed by the National Pressure Ulcer Advisory Panel (NPUAP, 2016b) as a quick, reliable tool to monitor the change in pressure injury status over time (Fig. 33-8 on page 1176). Graphing the PUSH Tool scores over time for each pressure injury allows health care providers to track whether the injury/ulcer is healing, remains unchanged, or is deteriorating (NPUAP, 2016b).

The RYB Wound Classification (red-yellow-black; see Box 33-5 on page 1171) can also be used to aid in assessment and description of the pressure injury appearance.

Pain Assessment

Nurses have long recognized that patients with alterations in skin integrity—including surgical wounds, traumatic wounds, and pressure ulcers—experience pain. Focus assessment on whether dressing changes, positioning in bed or in a chair, or movement elicits any expressions of pain. Perform a pain assessment at each dressing change; measure and document the level of pain before, during, and after a procedure. Even if pain is never verbalized or expressed, always assume that pain is a definite possibility, and focus on comfort needs (EPUAP, NPIAP, & PPPIA, 2019b). Ask the patient about pain from the wound and determine if the pain is a one-time episode of pain, occurs with dressing changes, or is constant (Baranoski & Ayello, 2020). If the patient experiences increased or constant pain from the wound, perform further assessments. Increasing pain, especially when accompanied by an increased or purulent flow of drainage, may indicate delayed healing or an infection (EPUAP, NPIAP, & PPPIA, 2019b). Surgical incisional pain

is usually most severe for the first 2 to 3 days and then progressively diminishes. Detailed assessment of pain is discussed in Chapter 36.

Diagnosing

Data that the nurse collect may lead to diagnosing actual or potential health problems or needs related to skin integrity and wound care. These identified problems and needs guide the development and communication of a coordinated plan that often involves the interprofessional team. Examples of patient problems and needs with related etiology and signs and symptoms can be found in the box titled Examples of Actual or Potential Health Problems and Needs: Patient with a Wound or Pressure Injury on page 1177.

Outcome Identification and Planning

When nurses care for patients who have or are at risk for altered skin and tissue integrity, nursing interventions are planned for returning the patient to health by facilitating wound healing, reducing the risk for complications, and promoting psychosocial adaptation. The following are examples of appropriate outcomes. The patient will:

- Maintain or restore skin integrity
- Demonstrate self-care measures to prevent pressure injury development
- Demonstrate self-care measures to promote wound healing
- Demonstrate evidence of wound healing
- Demonstrate increase in body weight and muscle size, if appropriate
- Remain free of infection at the site of the wound or pressure injury
- Remain free of signs and symptoms of infection
- Experience no new areas of skin breakdown
- Verbalize that the pain management regimen relieves pain to an acceptable level
- Demonstrate appropriate wound care measures before discharge
- Verbalize understanding of signs and symptoms to report and necessary follow-up care

NATIONAL PRESSURE ULCER ADVISORY PANEL

Pressure Ulcer Scale for Healing (PUSH)

PUSH Tool 3.0

Patient Name _____ Patient ID# _____

Ulcer Location _____ Date _____

Directions:

Observe and measure the pressure ulcer. Categorize the ulcer with respect to surface area, exudate, and type of wound tissue. Record a sub-score for each of these ulcer characteristics. Add the sub-scores to obtain the total score. A comparison of total scores measured over time provides an indication of the improvement or deterioration in pressure ulcer healing.

LENGTH X WIDTH (in cm^2)	**0** 0	**1** < 0.3	**2** 0.3 – 0.6	**3** 0.7 – 1.0	**4** 1.1 – 2.0	**5** 2.1 – 3.0	**Sub-score**
		6 3.1 – 4.0	**7** 4.1 – 8.0	**8** 8.1 – 12.0	**9** 12.1 – 24.0	**10** > 24.0	
EXUDATE AMOUNT	**0** None	**1** Light	**2** Moderate	**3** Heavy			**Sub-score**
TISSUE TYPE	**0** Closed	**1** Epithelial Tissue	**2** Granulation Tissue	**3** Slough	**4** Necrotic Tissue		**Sub-score**
							TOTAL SCORE

Length x Width: Measure the greatest length (head to toe) and the greatest width (side to side) using a centimeter ruler. Multiply these two measurements (length x width) to obtain an estimate of surface area in square centimeters (cm^2). Caveat: Do not guess! Always use a centimeter ruler and always use the same method each time the ulcer is measured.

Exudate Amount: Estimate the amount of exudate (drainage) present after removal of the dressing and before applying any topical agent to the ulcer. Estimate the exudate (drainage) as none, light, moderate, or heavy.

Tissue Type: This refers to the types of tissue that are present in the wound (ulcer) bed. Score as a "4" if there is any necrotic tissue present. Score as a "3" if there is any amount of slough present and necrotic tissue is absent. Score as a "2" if the wound is clean and contains granulation tissue. A superficial wound that is reepithelializing is scored as a "1". When the wound is closed, score as a "0".

- **4 – Necrotic Tissue (Eschar):** black, brown, or tan tissue that adheres firmly to the wound bed or ulcer edges and may be either firmer or softer than surrounding skin.
- **3 – Slough:** yellow or white tissue that adheres to the ulcer bed in strings or thick clumps, or is mucinous.
- **2 – Granulation Tissue:** pink or beefy red tissue with a shiny, moist, granular appearance.
- **1 – Epithelial Tissue:** for superficial ulcers, new pink or shiny tissue (skin) that grows in from the edges or as islands on the ulcer surface.
- **0 – Closed/Resurfaced:** the wound is completely covered with epithelium (new skin).

Examples of Actual or Potential Health Problems and Needs

PATIENT WITH A WOUND OR PRESSURE INJURY

Actual or Potential Health Problem or Need	Possible Etiologic Factors	Potential Signs and Symptoms
Altered Skin Integrity	• External factors: pressure on bony prominences; surgical incision; use of mobility or assistive devices; exposure to heat/cold, radiation therapy,	• Acute pain • Unintentional Injury: Open wound,

	or other agents • Patient-based: age, weight, nutritional and hydration status, medical history, general skin condition, mental status, mobility, incontinence, and hygiene	bleeding, hematoma/bruising, pressure injury/ulcer, shearing, burn • Intentional injury: surgical wound closed with staples, sutures, or another agent; open wound following surgical or chemical debridement
Pressure Injury Risk	• Pressure on bony prominences • Use of mobility-based or other equipment • Moisture and temperature variations on the skin • Debilitated or compromised state of the patient: mental or physical impairments, chronic or acute illness	—

Source: Wolters Kluwer. (2022). Problem-based care plans. In Lippincott Advisor. Wolters Kluwer. https://advisor.lww.com/lna/home.do

Implementing

Provide preventive measures for patients at risk for pressure injury. Teach patients about their health conditions and provide information and support to improve patients' health literacy. Refer to the accompanying Promoting Health Literacy display.

When caring for the patient with a wound or pressure injury, nursing interventions focus on preventing infection, promoting wound healing, preventing further injury or alteration in skin integrity, promoting physical and emotional comfort, and facilitating coping. It is often appropriate and necessary to consult with the wound care specialist, often a wound certified nurse specialist, to plan and coordinate the most effective care for the patient.

Preventing Pressure Injuries

Tissue load management refers to therapeutic means to manage pressure, friction, and shear on tissues (Baranoski & Ayello, 2020). Interventions to prevent injury to the skin and promote optimal health are outlined in Guidelines for Nursing Care 33-2 on page 1178. Additional interventions related to personal hygiene and maintaining skin health are discussed in Chapter 32. Implement interventions related to tissue load management as part of the nursing plan of care for patients at risk for developing pressure injuries or who have an existing pressure injury. This includes interventions that can be implemented while the patient is in bed and sitting in chairs or wheelchairs (see Skill 33-1, pages 1199–1201).

Promoting Health Literacy

IN PATIENTS WITH BREAST CANCER

Patient Scenario

Tashana Douglas, 42, has been diagnosed with breast cancer. She had a modified mastectomy 3 weeks ago and has returned to the clinic to discuss the rest of her treatment. She is going to have several weeks of outpatient radiation therapy. She states, "I feel pretty good, and the surgeon said my cancer is gone. Why do I need more treatment? My neighbor told me her sister had radiation and had terrible side effects." Ms. Douglas appears anxious as she relates that the neighbor's sister was extremely tired and had a "terrible rash or burn with her treatment. It took a long time to get better and really hurt." She states, "I don't know if I want to risk having that happen to me!" Ms. Douglas verbalizes concern that she will "give the radiation to others in her home and make them sick." She asks, "Do you think I should have this radiation stuff?"

Nursing Considerations: *Tips for Improving Health Literacy*

Review with Ms. Douglas the appropriate interventions she should be using to ensure that her surgical

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

site heals, including skin care. Provide Ms. Douglas with easy-to-read information about radiation therapy and potential side effects, as well as interventions she can implement to prevent and/or minimize the side effects of radiation therapy, particularly side effects related to skin integrity. Identify valid and reliable internet-based resources and discuss the importance of vetting the sites and information. Encourage her to ask her primary care provider, as well as the radiologist, as many questions as needed to understand her condition and the planned radiation treatment. Encourage Ms. Douglas to ask her primary care provider the following three questions:

- What is my main problem?
- What do I need to do?
- Why is it important for me to do this?

What additional measures can you take to help increase health literacy in this patient? What other measures would be helpful if Ms. Douglas does not speak English, cannot read, or has other learning deficits? How does her ability to *use* information, rather than just *understand* it, affect her autonomy, judgment, and decision making?

Guidelines for Nursing Care 33-2

PREVENTING PRESSURE INJURIES

- Assess the skin of patients at risk on a daily basis. Pay particular attention to bony prominences.
- Cleanse the skin routinely and whenever any soiling occurs. Use a mild cleansing agent, minimal friction, and avoid hot water.
- Maintain higher humidity in the environment and use skin moisturizers for dry skin.
- Avoid massage over bony prominences.
- Protect the skin from moisture associated with episodes of incontinence or exposure to wound drainage.
- Minimize skin injury from friction and shearing forces by using proper positioning, turning, and transferring techniques. Employ the use of appropriate equipment. Use lubricants, protective films, dressings, and padding to diminish the effects of friction on the skin.
- Use appropriate support surfaces (tissue load management surfaces).
- Investigate reasons for inadequate dietary intake of protein and calories. Administer nutritional supplements or more aggressive nutritional intervention as needed.
- Continue efforts to improve mobility and activity. If this is unrealistic, attempt to maintain current level of activity, mobility, and range of motion.
- Document measures used to prevent pressure injuries and the results of these interventions.

To protect patients at risk from the adverse effects of pressure, implement turning and positioning schedules, as well as the use of appropriate support surfaces (tissue load management surfaces). Follow facility protocols regarding repositioning, which may indicate turning bed-bound patients every two hours and repositioning chair-bound patients every hour. Teach patients to make subtle position changes frequently, including pressure-relieving maneuvers (such as lifts) as appropriate (EPUAP, NPIAP, & PPPIA, 2019b). Older adult patients tend to have less tissue tolerance, necessitating more frequent repositioning if redness on bony prominences is noted. The oblique position, an alternative to the side-lying position, results in significantly less pressure on the trochanter area. Do not position the head of the bed above 30 degrees unless medically contraindicated, and alternate right side, back, left side, and prone positions (when tolerated) using appropriate equipment to minimize friction and shearing (EPUAP, NPIAP, & PPPIA, 2019b). The best approach to turning and repositioning is to evaluate and reevaluate each patient to best determine an appropriate turning schedule (Baranoski & Ayello, 2020). See the accompanying Research in Nursing box on page 1174, which highlights the importance of the nurse's role in the prevention of pressure injuries.

Positioning devices such as pillows, foam wedges, or pressure-reducing boots can prove helpful to keep body weight off bony prominences. For example, unless contraindicated, a standard pillow placed under the length of the calves raises the heels off the bed and alleviates pressure. Never use ring cushions, or *donuts*, because they increase venous pressure. Minimize the effects of shearing force by limiting the amount of time the head of the bed is elevated, when possible.

Support surfaces are an important part of managing pressure, friction, and shear on tissues (Baranoski & Ayello, 2020). A support surface is a "specialized device for pressure redistribution designed for management of tissue loads, micro-climate, and/or other therapeutic functions" (NPIAP, 2019, p. 5). Support surfaces are available in sizes and shapes to be used on beds, chairs, examination tables, and operating room tables. Support surfaces are pressure-reducing or pressure-relieving devices. The most common support surfaces are seating devices (air, fluid foam, or gel

cushions); air-, gel-, or water-filled mattress overlays; static flotation mattresses; alternating air mattresses; low–air-loss beds; and air-fluidized beds. It is important to individualize the type of support surface based on the patient's needs. Some support surfaces allow for an extended length of time between position changes. Because none of these devices totally relieves pressure, continues to perform position changes at regular intervals.

The use of appropriate devices to ensure safe patient handling and movement is an important part of tissue load management. Use friction-reducing sheets and lifting devices with patients who cannot assist during transfers and position changes. These interventions and devices are discussed at length in Chapter 34.

Wound Care/Wound Management

The goal of wound care is to promote tissue repair and regeneration so that skin integrity is restored. Wounds can be treated by leaving them open to air; no **dressing** (protective covering placed over a wound) is applied. Wounds left open to air heal more slowly because wound drying produces a dried eschar or scab. If the scab is removed accidentally before healing is complete, reinjury occurs, and the new delicate cells are exposed. Wounds left open are exposed to more environmental factors and potential injury.

Closed wound care uses dressings to keep the wound moist, promoting healing. A moist environment is best for wound healing. When a dressing is placed over a wound, the wound fluid keeps the surface of the wound moist. As a result, epidermal cells migrate more rapidly, maximizing healing. In addition, covered wounds can help patients cope with alterations in body image.

In general, an ideal dressing should maintain a moist environment, be absorbent, provide thermal insulation, act as a bacterial barrier, reduce or eliminate pain at the wound site, and allow for pain-free removal (Baranoski & Ayello, 2020; Hess, 2019). Choosing a dressing or device for wound management needs to take into consideration wound- and skin-related factors, patient-related factors, and dressing-related factors (Hess, 2019). Many different types of dressings are available, but all have essentially the same purposes:

- Provide physical, psychological, and aesthetic comfort
- Prevent, eliminate, or control infection
- Absorb drainage (exudate)
- Maintain moisture balance of the wound
- Protect the wound from further injury
- Protect the skin surrounding the wound
- Debride (remove damaged/necrotic tissue), if appropriate
- Stimulate and/or optimize the healing response
- Consider ease of use and cost effectiveness

There is no standard frequency for how often dressings should be changed. It depends on the amount of drainage, the primary provider's preference, the nature of the wound, and the particular wound care product being used. It is customary for the surgeon or other advanced practice provider to perform the first dressing change on a surgical wound, usually within 24 to 48 hours after surgery.

Consider the care needed by **Lucius Everly**, the patient in the critical care unit. Although he has multiple needs, performing incisional wound care cannot be overlooked; otherwise, his risk of infection may increase.

Wound contamination occurs through a moist medium. Microorganisms can move from the external surface through the dressing to the wound if a dressing remains in place until it is saturated. Microorganisms can also move from the wound to the outer surface of a saturated dressing. For these reasons, always replace dressings with fresh dressings or reinforce the dressing with additional dressings before drainage causes saturation.

Dressing changes provide an excellent opportunity for teaching, which is especially important when the patient will be changing dressings at home. Encourage the patient to help as much as possible, if appropriate.

The sight of the wound may disturb a patient. Listen carefully to what the patient is saying and observe nonverbal communication as well. In some instances, the patient may not want to look at the wound, particularly with a wound that involves a change in normal body functions or appearance, such as a wound resulting from the removal of a breast, the amputation of an extremity, or the placement of a tube in a draining wound. With patience and emotional support, patients can learn to cope with and adapt to their wound.

TYPES OF WOUND DRESSINGS

The items needed for a dressing change may be gathered individually or may be packaged in a sterile dressing tray, depending on the health care setting. Wound care in the home may depend on the supplies provided by the patient or family.

The number and type of dressings used depend on the location and size of the wound, type and depth of wound, the presence of infection, the need for **debridement** (removal of devitalized tissue and foreign material), and the amount and type of drainage. There are many dressing types and manufacturers (Hess, 2019)—the nurse needs to collaborate with the health care provider to ensure the correct dressing type is chosen, ongoing assessment occurs, and updates to the treatment plan (dressing choice) are made as the wound evolves.

There are three basic types of primary dressings: those that maintain moisture, those that absorb moisture, and those that add moisture (Baranoski & Ayello, 2020). Dry gauze dressings can be used to cover wounds, commonly closed surgical wounds. These dressings come in various sizes (2 × 2 inch, 4 × 4 inch, 4 × 8 inch) and are commercially packaged as single units or in packs. Gauze dressings often consist of three layers. The first layer of dressing material applied directly to a draining wound is often nonabsorbent but hydrophilic (i.e., capable of carrying moisture). This type of material allows drainage from the wound to move into overlying absorbent layers of dressing, helping to prevent maceration and reinfection. Moreover, this type of dressing is less likely to stick to the wound, making dressing changes more comfortable for the patient.

Material to absorb and collect drainage is then placed over the first layer of nonabsorbent material. This material acts as a wick, pulling drainage out by capillary action. Absorbent cotton has far greater capillarity than untreated cotton. Therefore, cotton-lined gauze sponges soak up more liquid than do unlined sponges. The number of gauze sponges used in the dressing depends on the amount of drainage. The wound may also be packed with gauze or another material. Loosely packed gauze, the threads of which act as numerous wicks, enhances capillarity, and directs drainage upward and away from the wound. Fluffed and loosely packed dressings are more absorbent than tightly packed dressings. The top of the dressing may be further protected by surgical or abdominal pads (ABDs), which are thick, absorbent pads that help to absorb profuse drainage (Fig. 33-9).

Nonadherent gauzes include sterile petrolatum gauze and Telfa gauze. Telfa's shiny outer surface is applied to the wound. These dressings allow drainage to pass through and be absorbed by the outer absorbent layer but prevent outer dressings from adhering to the wound and causing further injury when removed. These dressings are often used on incisions closed with sutures or staples.

FIGURE 33-9. Surgical pad applied as last layer of wound dressing.

FIGURE 33-10. Precut dressing placed around surgical drain.

Special gauze dressings (e.g., Sof-Wick) are precut halfway to fit around drains or tubes (Fig. 33-10). Larger dressings (8 × 10 bandages, abdominal pads [ABDs], Surgi-Pads) are placed over the smaller gauze dressings and absorb drainage and protect the wound from contamination or injury.

Transparent films (e.g., OPSITE) are semipermeable membrane dressings that are adhesive and waterproof. These dressings are occlusive, decreasing the possibility of contamination, while allowing visualization of the wound. This type of dressing is often used over peripheral intravenous sites, central venous access device insertion sites, and noninfected healing wounds (Fig. 33-11).

Think back to **Lucius Everly**, the patient in the critical care unit. The nurse most likely would use a transparent dressing on his venous access sites, thereby allowing frequent assessment of the sites.

FIGURE 33-11. Transparent film dressing placed on intravenous access site.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 33-12. Hydrocolloid dressing in place on wound.

When caring for open wounds and pressure injuries, it is necessary to keep the wound tissue moist and the surrounding skin dry. Therefore, use dressings that continuously keep the wound moist, placing the moist dressing only on the wound surface and keeping the intact, healthy skin surrounding the ulcer dry because it is susceptible to damage. Select a dressing that absorbs exudate, if present, but still maintains a moist environment for healing. Use a skin sealant or moisture-barrier ointment on the surrounding skin and secure the dressing with the least amount of tape or other material to secure that is necessary.

The presence of foreign matter and/or devitalized, injured, infected tissue in a wound may indicate the need for debridement to promote wound healing (Baranoski & Ayello, 2020). Debridement can be accomplished through several different methods. Autolytic debridement uses occlusive dressings, such as hydrocolloids (Fig. 33-12) or transparent films, and uses the body's own enzymes and defense mechanisms to loosen and liquefy necrotic tissue. Enzymatic debridement involves the application of commercially prepared enzymes to speed up the body's autolytic process. Mechanical debridement uses external physical force to dislodge and remove debris and necrotic tissue. This could be achieved by wound irrigation with pulsed pressure lavage (washing), whirlpool therapy, ultrasound or laser treatment, or with surgical debridement. In the past, wet-to-dry gauze dressings have been used to debride wounds, but this is no longer considered good practice. This type of dressing damages healthy wound bed tissue and can be painful (Baranoski & Ayello, 2020). Concern exists that complete drying of the gauze disrupts angiogenesis. However, despite concerns by wound care experts, these dressings are still prescribed by health care providers for wound debridement. When possible, use a product designed to promote moisture balance; do not use dry gauze in an open wound.

There are many other wound care products/dressings available, each with distinctive actions, as well as indications, contraindications, advantages, and disadvantages. It is very important for the nurse to be aware of the products available in a particular facility and be familiar with the indications for, and correct use of, each type of dressing and wound care product. A wound with heavy exudate will need a more absorptive dressing, and a dry wound will require rehydration with a dressing that keeps the wound moist. Table 33-5 (on pages 1182–1183) outlines the purposes and uses for several wound dressing/product categories. Advances in wound care now include *smart* dressings, which have embedded sensors, microprocessors, and communication devices (O'Callaghan et al., 2020)—watch for continued advances in commercially available wound dressings.

Technology Alert

Smart dressings are changing the way we care for wounds by providing information through sensors, microprocessors, and communication devices.

CHANGING THE DRESSING

Prepare the patient for the dressing change before starting the procedure by explaining what will be done. If wound care is uncomfortable, administer a prescribed analgesic 30 to 45 minutes before changing the dressing. Also, plan to change the dressing midway between meals so that the patient's appetite and mealtimes are not disturbed.

Provide privacy by properly screening the patient; close the room door and curtain. Help the patient into a position that is comfortable but convenient for changing the dressing. Expose only the area necessary to perform the wound care while maintaining proper draping.

Using appropriate aseptic techniques when changing the dressing is crucial. The Aseptic Non Touch Technique (ANTT® , 2019) provides an international set of principles and specific framework designed to standardize safe aseptic practice and decrease the risk of infection. One component of the ANTT® framework addresses the essential nontouch technique. In the nontouch technique, the practitioner touches a site or equipment only as absolutely necessary, even

when wearing sterile gloves. For example, when placing a dressing, the nurse will not touch the side of the dressing that will be in direct contact with the wound. Integrating core principles, such as the nontouch technique, into both routine nursing practice and agency guidelines, policies, and protocols is essential (ANTT® , 2019; Sonoiki et al., 2020). Be especially vigilant in performing hand hygiene thoroughly before and after changing dressings. Remember and adhere to standard precautions and transmission-based precautions, when necessary. Among the most common causes of hospital-acquired infections is carelessness in practicing asepsis during dressing changes. Surgical wounds that have dehisced require the use of sterile technique. Pressure injuries are nonsterile wounds, so there is no need to use sterile dressings on these wounds (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019b). Nonsterile gloves can be used to perform clean wound care.

Concept Mastery Alert

A helpful way to remember which technique to use for wound care is this: Surgery occurs under sterile conditions, so open surgical wounds = sterile technique; pressure injuries = clean technique.

Removing a Dressing

Remove any dressing currently in place:

- Use standard precautions; use appropriate transmission-based precautions when indicated.
- Perform hand hygiene and put on clean (nonsterile) gloves.
- Remove tape and dressings in the direction of hair growth to minimize trauma to the skin. Using two hands and a low angle parallel to the skin, remove adhesives slowly while supporting the skin where it is attached to the tape/adhesive (Yates et al., 2017). Use a push–pull method; lift a corner of the dressing away from the skin, then gently push the skin away from the dressing/adhesive. Continue moving fingers of the opposite hand to support the skin as the product is removed (McNichol et al., 2013).
- Carefully lift the adhesive barrier from the surrounding skin to prevent medical adhesive–related skin injury (MARSI). Remove the sides/edges first, then the center. If there is resistance, use an adhesive remover (per manufacturer recommendations) for easy, rapid, and painless removal without the associated problems of skin stripping (McNichol et al., 2013; Yates et al., 2017).
- Slowly remove the dressing, noting the amount, type, color, and odor of the drainage.
- Discard the dressing according to facility policy.
- Remove gloves and perform hand hygiene.

Cleaning the Wound

Perform wound cleaning to remove microorganisms and debris with as little chemical and mechanical force as possible and protect healthy granulation tissue. Normal saline solution (0.9% sodium chloride) or cleansing solutions with antimicrobials are recommended, particularly when cleaning pressure injury wounds. There are also commercially prepared cleansing sprays, typically antiseptics or surfactants, available for use in wounds with debris, confirmed infection, or high levels of bacterial colonization (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019b).

Wounds are cleaned initially and before applying any new dressing. Guidelines for Nursing Care 33-3 on page 1184 outlines the techniques for cleaning a wound with approximated edges, such as a surgical incision, and for cleaning a wound with edges that are not approximated to remove cellular debris and drainage. Wound irrigation is a directed flow of solution over tissues. Sterile equipment and solutions are required for irrigating an open wound, even in the presence of an existing infection. Sterile 0.9% sodium chloride or sterile water, a commercially prepared wound cleanser, an antiseptic, or an antibiotic solution may be used, depending on the condition of the wound and the primary health care provider's prescription. A sterile, large-volume syringe is used to direct the flow of the solution. After irrigation, open wounds may be packed and dressed with appropriate materials to absorb additional drainage and allow healing by secondary intention to take place (see Table 33-5 on pages 1182–1183). Nonsterile solutions are generally used to clean the skin surface if the wound edges are approximated.

Table 33-5 Examples of Wound Dressings/Products

TYPE	PURPOSES	USE
Transparent films, such as: 3M™ Tegaderm™ BIOCLUSIVE™ Plus Transparent Film Dressing DermaView	• Allow exchange of oxygen between wound and environment • Are self-adhesive • Protect against contamination; waterproof	• Wounds that are small; partial thickness • May remain in place for 4–7 days, resulting in less interference with healing • Stage 1 pressure injuries

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

OPSITE™	• Prevent loss of wound fluid • Maintain a moist wound environment • Facilitate autolytic debridement • No absorption of drainage • Allow visualization of wound	• Wounds with minimal drainage • Cover dressings for gels, foams, and gauze • Secure intravenous catheters, nasal cannulas, chest tube dressing, central venous access devices
Hydrocolloid dressings, such as: Comfeel® Plus Sacral Dressing DermaFilm Thin DuoDERM® CGF Dressing Hydrocolloid Dressing 3M™ Restore™ Hydrocolloid Dressing	• Are occlusive or semiocclusive, limiting exchange of oxygen between wound and environment • Inner layer is self-adherent, gel forming, and composed of colloid particles • Outer layer seals and protects the wound from contamination • Minimal to moderate absorption of drainage • Maintain a moist wound environment • Thermal insulation • Provide cushioning • Facilitate autolytic debridement • May remain in place for 3–7 days, depending on exudate	• Partial- and full-thickness wounds • Stage 2 and stage 3 pressure injuries • Prevention at high-risk friction areas • Wounds with light to moderate drainage • Wounds with necrosis or slough • First- and second-degree burns • Not for use with wounds that are infected
Hydrogels, such as: AquaDerm DermaGauze Elasto-Gel™ Island Hydrogel INTRASITE Gel Hydrogel Wound Dressing	• Polymer gels comprised of an 80–99% water base • Available in many sizes and forms (gels, sheets, gauze, strips) • Maintain a moist wound environment • Minimal absorption of drainage • Facilitate autolytic debridement • Thermal insulation • Do not adhere to wound • Less effective barrier than occlusive dressings • Reduce pain • Most require a secondary dressing to secure • May remain in place for 24–72 hours, depending on the gel form	• Partial- and full-thickness wounds • Stages 2–4 pressure injuries • Necrotic wounds • First- and second-degree burns • Dry wounds • Wounds with minimal exudate • Infected wounds • Radiation tissue damage
Alginates, such as: AQUACEL® EXTRA Wound Dressing Eclypse® Super Absorbent Dressing KALTOSTAT® Wound Dressing Melgisorb® Plus Alginate Dressing	• Contain alginic acid from brown seaweed; covered in calcium–sodium salts • Absorb exudate • Maintain a moist wound environment • Facilitate autolytic debridement • Require secondary dressing	• Partial- and full-thickness wounds • May remain in place for 1–3 days • Stage 3 and stage 4 pressure injuries • Infected and noninfected wounds • Wounds with moderate to heavy exudate • Tunneling wounds; undermining • Moist red and yellow wounds • Not for use with wounds with minimal

	to secure	drainage or dry eschar
Foams, such as: 3M™ Tegaderm™ Foam Adhesive Dressing Advazorb® Heel Hydrophilic Foam Dressings Mepilex® Absorbent Foam Dressing Optifoam Gentle POLYDERM Plus Barrier Foam Dressing PolyMem® Dressing	• Foam covered by hydrophilic polyurethane or gel • Maintain a moist wound environment • Do not adhere to wound • Insulate wound • Highly absorbent • May require a secondary dressing to secure	• Partial- and full-thickness wounds • May remain in place 3–5 days (7 days for foams with silver), depending on exudate • Stages 2–4 pressure injuries • Surgical wounds • Absorb light to heavy amounts of drainage • Use around tubes and drains • Not for use with wounds with dry eschar
Antimicrobials, such as: AQUACEL™ Ag Surgical Wound Dressing Mepilex® Ag Antimicrobial Foam Dressing Optifoam Ag+ Post-Op PolyMem® Silver™ Dressing	• Antimicrobial or antibacterial action (reduce and/or prevent infection) • Do not adhere to wound • Can be highly absorbent • May require a secondary dressing to secure • Antimicrobial action may last 7 days	• Partial- and full-thickness wounds • Stages 2–4 pressure injuries • Burns • Primary dressing over skin graft(s) and donor sites • Draining, exuding, and nonhealing wounds of any kind (pressure injury, venous/arterial, diabetic, surgical) • Acute and chronic wounds
Collagens, such as: DermaCOL PROMOGRAN™ Matrix Wound Dressing Stimulen™	• Protein (collagen derived from bovine, porcine, or avian sources) stimulates cellular migration and fosters new tissue development • Highly absorbent • Maintain a moist wound environment • Do not adhere to wound • Compatible with topical agents • Conform well to the wound surface • Require secondary dressing to secure • May remain in place 3–5 days (7 days for foams with silver), depending on exudate	• Partial- or full-thickness wounds • Stage 3 pressure injuries • Infected and noninfected wounds • Primary dressing over skin graft(s) and donor sites • Tunneling wounds • Moist red and yellow wounds
Contact layers, such as: ADAPTIC TOUCH™ Non-Adhering Silicone Dressing Profore WCL Silflex® Silicone Contact Layer	• Placed in contact with base of wound, protecting base from trauma during dressing change • Allow exudate to pass to a secondary dressing • Not intended to be changed with every dressing change • May be used with topical medication, wound filler, or gauze dressings	• Partial- and full-thickness wounds • Require secondary dressing to secure • Shallow, dehydrated wounds • Wounds with eschar • Wounds with viscous exudate
Composites, such as: 3M™ Tegaderm™ Absorbant Clear Acrylic	• Combine two or more physically distinct products in a single dressing with several functions	• Partial- and full-thickness wounds • Primary or secondary dressing • Stages 1–4 pressure injures

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Dressing Covaderm Plus Stratasorb	• Allow exchange of oxygen between wound and environment • May facilitate autolytic debridement • Provide physical bacterial barrier and absorptive layer • Semiadherent or nonadherent	• Wounds with minimal to heavy exudate • Necrotic tissue • Mixed (granulation and necrotic tissue) wounds • Infected wounds
Cellular and tissue-based products (CPTs) AlloSkin™ Grafix CORE®	• Nonviable or viable human or animal cells, tissue-based from humans and animals	• Partial- and full-thickness wounds • Venous and diabetic ulcers • Burns • Chronic wounds
Negative pressure wound therapy (NPWT), such as: Avelle™ Negative Pressure Wound Therapy System V.A.C.® Therapy	• Noninvasive device that applies pressure to the wound bed through a unit attached to a dressing/sponge (various foam densities) • Highly absorbent • Decreases bacterial colonization • Stimulates increased blood supply and granulation	• Partial- and full-thickness wounds • May remain in place 2–3 days, depending on manufacturer recommendations • Stage 3 and stage 4 pressure injuries • Draining, exuding, and nonhealing wounds of any kind (pressure injury, venous/arterial, diabetic, surgical, dehisced)

Guidelines for Nursing Care 33-3

CLEANING WOUNDS

Cleaning Wounds With Approximated Edges

- Use standard precautions; use appropriate transmission-based precautions when indicated.
- Moisten a sterile gauze pad or swab with the prescribed cleansing agent.
- Use a new swab or gauze for each downward stroke.
- Clean from top to bottom.
- Work outward from the incision in lines parallel to it (Figure A).
- Wipe from the clean area toward the less clean area.

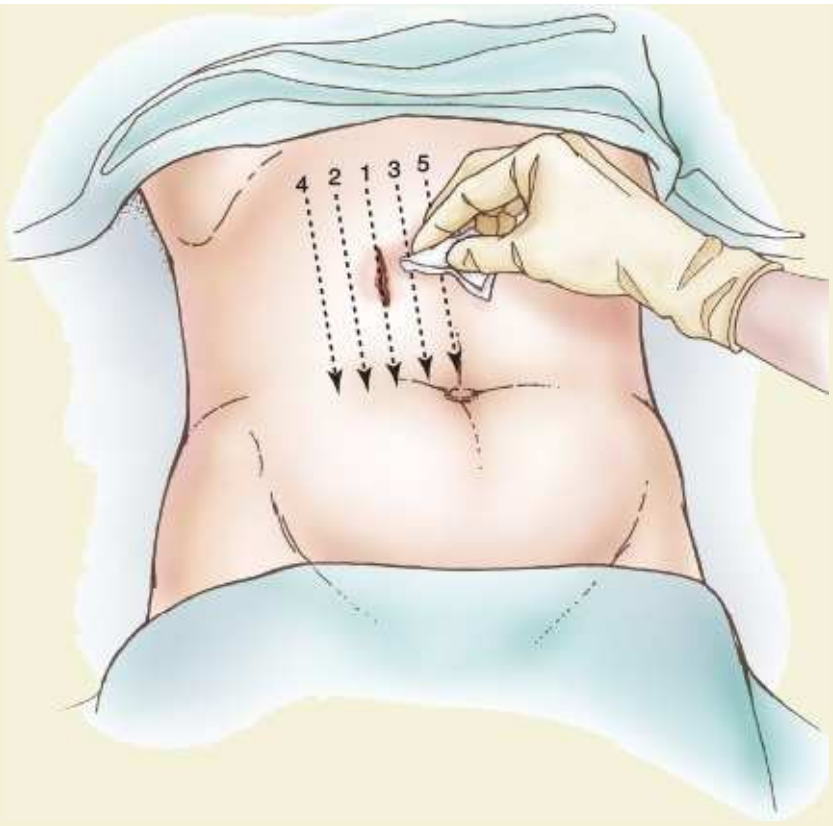

FIGURE A

Cleaning Wounds With Edges That Are Not Approximated

- Use standard precautions; use appropriate transmission-based precautions when indicated.
- Moisten a sterile gauze pad or swab with the prescribed cleansing agent and squeeze out excess solution.
- Use a new swab or gauze for each circle.
- Clean the wound in full or half circles, beginning in the center and working toward the outside (Figure B).
- Clean to at least 1 inch beyond the end of the new dressing.
- If a dressing is not being applied, clean to at least 2 inches beyond the wound margins.

FIGURE B

Source: Hess, C. (2013). *Clinical guide to skin & wound care* (7th ed.). Wolters Kluwer.

Applying a New Dressing

Ensure that the area is clean and dry. Apply a skin protectant or barrier to the healthy skin around the wound. This is particularly important if there is drainage from the wound. The skin protectant prevents skin irritation and excoriation from tape, adhesives, and wound drainage (McNichol et al., 2013).

The nurse should be familiar with and follow the manufacturer's guidelines for the specific dressing in use (Hess, 2019). General guidelines for applying a new dressing include:

- Check the wound care order or nursing care plan.
- Perform hand hygiene.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Use standard precautions; use appropriate transmission-based precautions when indicated.

- Check the patient's identification.
- Explain what you are going to do to the patient.
- Provide privacy by closing the door to the room and pulling the bedside curtain.
- Put on gloves.
- Cleanse the wound, and periwound skin, as prescribed.
- Apply a skin barrier, such as Skin Prep, to the areas of skin where the dressing adhesive or tape will be placed and to areas around the wound where drainage may come in contact with skin.
- Apply any topical medications, foams, gels, and/or gauze to the wound as prescribed; ensure products stay confined to the wound and do not impact on intact surrounding tissue/skin.
- Gently place the dressing at the wound center and extend it at least 1 in beyond the wound in each direction. Alternatively, follow the manufacturer's directions for application.
- Remove gloves when the dressing is in place, before handling tape, if used.
- Do not apply tape under tension to prevent blisters and skin shearing.
- Perform hand hygiene.

Table 33-6 Popular Types of Tape

TYPE	PURPOSE
Micropore Paper Tape (hypoallergenic)	Paper tape Gentle, yet secure adhesion Good for sensitive skin Sticks to skin, other tape, and dressings Breathable and easy to tear
Transpore Polyethylene Tape (hypoallergenic)	Transparent plastic tape Adheres even when wet Often used to secure tubes and drains Breathable and perforated for easy tearing
Durable Cloth Tape	Silk-like cloth tape Flexible and comfortable Adheres well to skin Conforms to bony prominences Breathable and tears in any direction
Coban or Other Self Adherent Wrap	Sticks to itself—no adhesive, pins, or clips Breathable and lightweight Can be used for compression

Skill 33-2 on pages 1203–1208 describes cleaning a wound and applying a saline-moistened dressing. Skill 33-3 on pages 1208–1212 presents the technique for irrigating a wound.

Securing Wound Dressings

Many dressings are self-adhesive; therefore, no further material is needed to secure the dressing in place over the wound. However, other wound dressings require additional materials to hold the dressings in place, including tape, bandages and binders, and Montgomery straps.

Tape can be used to secure dressings in place. Tape comes in a wide variety of sizes and types, ranging in width from 1 to 4 inches (1-inch-wide tape is the most commonly used). Take care to protect the skin surrounding the wound from injury-related irritation or shearing or tearing of the skin during tape removal. Table 33-6 summarizes the types and purposes of different tapes.

Bandages and *binders* are used to secure dressings, apply pressure, and support the wound. **Bandages** are strips of cloth, gauze (e.g., roller gauze, Kerlix, Kling), or elasticized material (e.g., ACE bandages) used to wrap a body part. They come packaged in rolls and vary in width from 1 to 6 inches. Binders are designed for a specific body part and include slings, abdominal binders, chest binders, and T-binders. They may be made of cloth (flannel, muslin) or of an elasticized material that fastens together with Velcro. Guidelines for Nursing Care 33-4 highlights important principles for applying bandages and binders.

A *roller bandage* is a continuous strip of material wound on itself to form a cylinder or roll. Plain gauze, elastic

webbing, and stretchable roller bandages are made in various widths and lengths. Begin applying the bandage to the distal part of the area. The free end is held in place with one hand while the other hand passes the roll around the body part. After the bandage is anchored, the roll is passed or rolled around the body part, taking care to exert equal tension in all turns and rolling toward the heart, to avoid causing venous stasis and resulting edema. Apply the bandage using a circular turn, spiral turn, or figure-of-eight turn (Fig. 33-13 on page 1186). For each technique, keep tension equal by unwinding the bandage gradually and only with as much length as is required. Evenly overlap one half to two thirds the width of the bandage with each turn, except for the circular turn. A circular turn is used primarily to anchor a bandage. In a circular turn, wrap the bandage around the body part, completely overlapping the previous bandage turn. Once the circular turn anchors the bandage, application continues, ascending in a spiral manner using a spiral turn. Each turn overlaps the preceding one by one half or two thirds the width of the bandage. The spiral turn is useful for the wrist, fingers, and trunk. The figure-of-eight turn consists of making oblique overlapping turns that ascend and descend alternatively. It is effective for use around joints, such as the knee, elbow, ankle, and wrist. When removing a roller bandage, cut the bandage with bandage scissors to prevent excessive manipulation of the part. Cut on the side opposite the injury or the wound, from one end to the other, so that the bandage can be folded open for its entire length. If the bandage is to be reused, it may be unwound by keeping the loose ends together and passing it as a ball from one hand to the other while unwinding it.

When applying a *recurrent bandage,* make a few circular turns to anchor the bandage, and place the initial end of the bandage at the center of the body part being bandaged, well back from the tip to be covered. Pass the bandage back and forth over the tip, first on the one side and then on the other side of the centerpiece of the bandage. Figure 33-13 shows how to apply a recurrent bandage to a residual limb, using the figure-of-eight turn to finish the bandage. Recurrent bandages are used for fingers, for the head, and for a residual limb.

Guidelines for Nursing Care 33-4

APPLYING BANDAGES AND BINDERS

- Clean the area to be covered and dry it thoroughly before applying a bandage or binder, because prolonged heat and moisture on the skin may cause skin breakdown.
- Bandage the body part in the normal functioning position to prevent deformities and discomfort.
- Apply the bandage or binder with sufficient pressure to provide the amount of immobilization or support desired, to remain in place, and to secure a dressing when present. Do not apply pressure to such a degree that circulation to the involved body part is impeded.
- Maintain equal tension with all bandage turns; avoid unnecessary and uneven overlapping of turns.
- After application, assess circulation and comfort at regular intervals.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

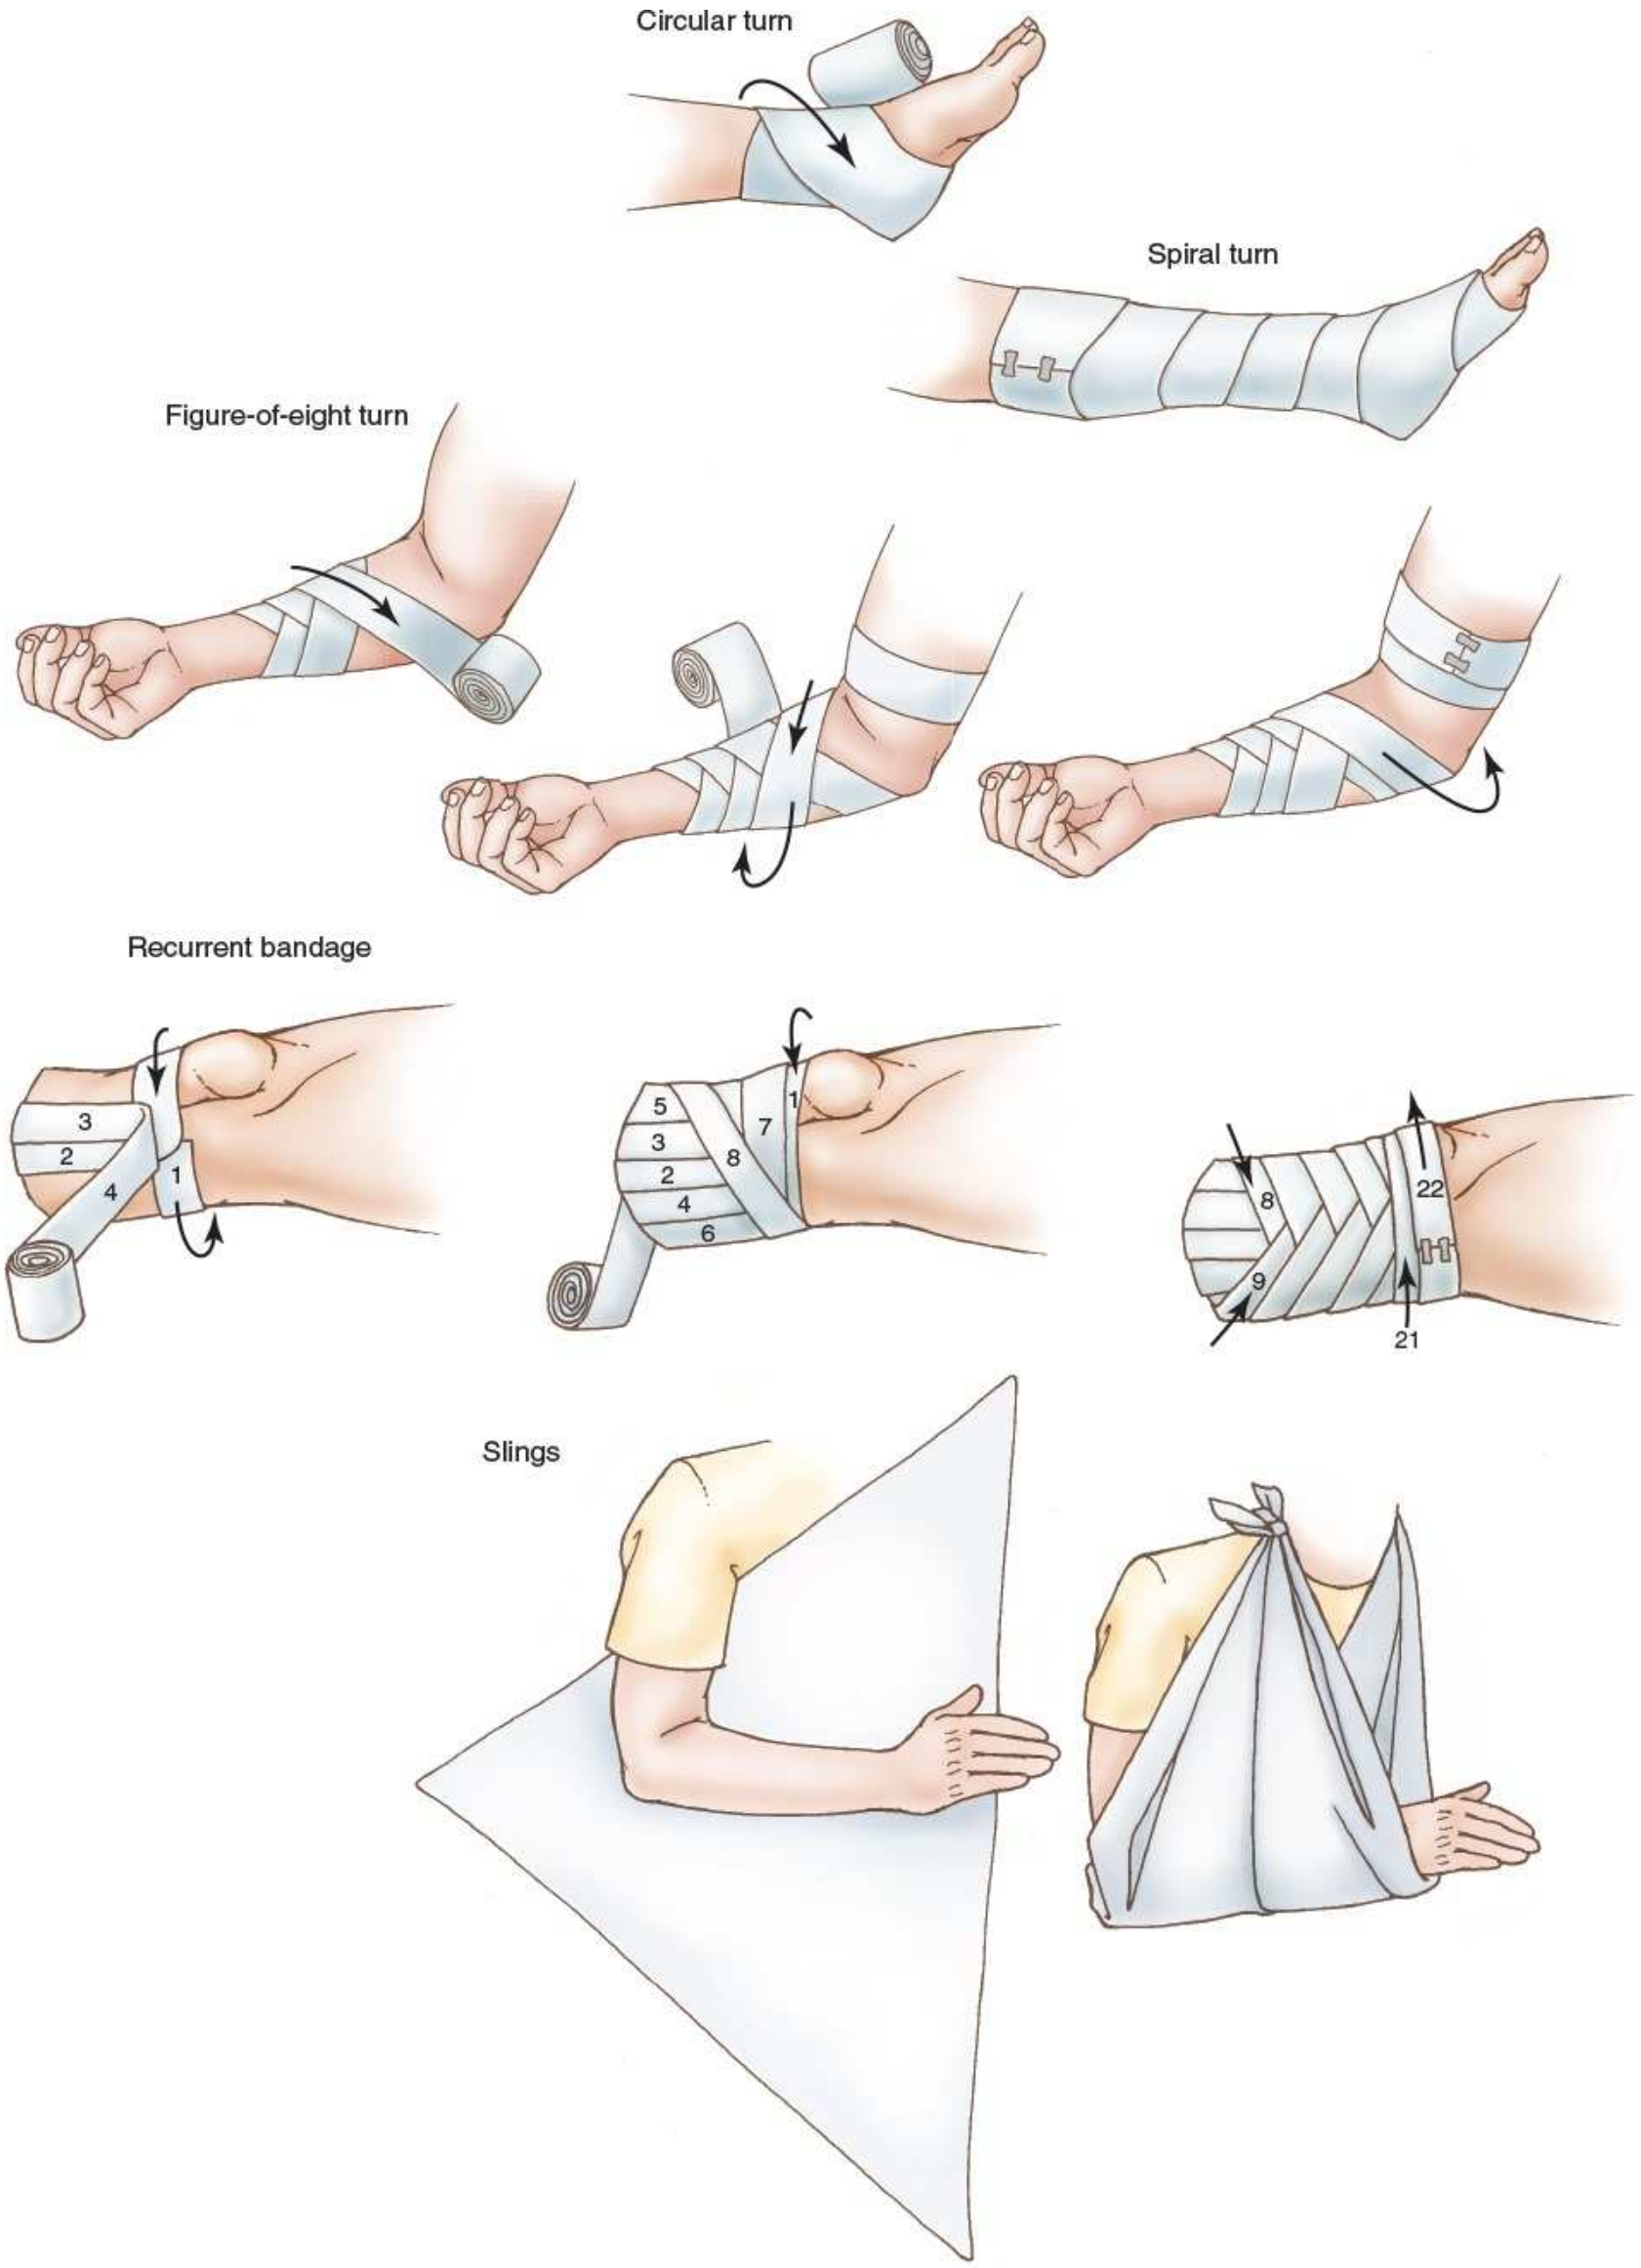

FIGURE 33-13. Techniques for applying various bandages.

Of the many different kinds of *binders,* those used most commonly include straight binders, T-binders, and slings. A straight binder is a straight piece of material, usually about 15 to 20 cm (6 to 8 inches) wide and long enough to more than circle the torso. It is used for the chest and the abdomen. Straight binders may be pinned or, more commonly, fastened with Velcro.

A T-binder might be used to secure dressings on the rectum and perineum and in the groin. Although not used often in the hospital, these are sometimes used in the home care setting. The single T-binder is used for female patients, the double T-binder for male patients. Pass the belt around the waist and secure it, then pass the tails between the legs and fasten them to the belt.

A sling is used to support an arm. Most health care facilities use commercial strap slings or sleeve slings. In the home, a large piece of cloth folded into a triangle can be used as a sling (see Fig. 33-13).

Montgomery straps use ties attached to an adhesive backing to hold dressings in place. Newer devices and advances in skin care adhesives have led to a decreased use of Montgomery straps, but the concept is important to review. Protect the patient's skin with a skin barrier, such as Skin Prep, or a hydrocolloid dressing, prior to applying the Montgomery straps. Apply the adhesive backing to the skin adjacent to the wound, with the ties extending over the wound area. When the dressing is changed, untie the strips and turn them back to allow for wound care. After applying the new dressing, tie the straps over the dressing to hold it in place. Montgomery straps can be useful in preventing skin irritation and damage due to constant retaping with dressing changes. Change Montgomery straps only when they become moist or soiled.

Caring for Patients With Wound Drains

A variety of drains, catheters, or tubes may be inserted into or near a wound when it is anticipated that a collection of fluid in a closed area would delay healing. After a surgical procedure, the surgeon places one end of the tube or drain in or near the area to be drained and passes the other end through the skin, either directly through the incision or through a separate opening called a stab wound. Wound drains are either open systems that drain into dressings or closed systems that drain into a suction device. Drains and tubes may or may not be sutured in place.

OPEN DRAINAGE SYSTEMS

A Penrose drain is soft and flexible. This drain does not have a collection device. It empties into absorptive dressing material. It promotes drainage passively, with the drainage moving from the area of greater pressure, in the wound or surgical site, to the area of less pressure, the dressing. It is not sutured in place. A sterile, large safety pin or small tab is often attached to the outer portion to prevent the drain from slipping back into the incised area (Fig. 33-14). Care is necessary to ensure that these drains are not dislodged during dressing changes. Sometimes the health care provider orders a Penrose drain that is to be shortened each day. To do so, grasp the end of the drain with sterile forceps, pull it out a short distance while using a twisting motion, and cut off the end of the drain with sterile scissors. Place a new sterile pin or small tab at the base of the drain, as close to the skin as possible.

FIGURE 33-14. Penrose drain.

CLOSED DRAINAGE SYSTEMS

Closed drainage systems consist of a drainage tube that may be connected to an electrical suction device or have a portable built-in reservoir to maintain constant low suction. Examples include Jackson-Pratt drainage tubes (Fig. 33-15 on page 1188), Hemovacs (Fig. 33-16 on page 1188), and Blake drains, which have four drainage channels within the silicon tube. These tubes are usually sutured to the skin. The closed drainage system prevents microorganisms from entering the wound from saturated dressings. Closed drainage systems also allow accurate measurement of drainage. Be sure to know which type of drain or tube was inserted during surgery to ensure accurate assessments and interventions. These systems must be emptied, and the suction reestablished according to the directions for each device. This usually involves compressing the container while the port is open, then closing the port after the device is compressed. Skills 33-4 on pages 1212–1217 and 33-5 on pages 1217–1220 outline the procedures for caring for Jackson-Pratt and Hemovac drains. Wear gloves when emptying the drainage and do not touch the open port to avoid contaminating the port. If the device ever fully expands, meaning no suction is being applied, empty the device and reengage the suction. Although a surgical or percutaneous drain will likely always produce some output, drains are removed at different times, depending on the intention, location, and procedure. In general, drains are removed by the nurse or provider when the output color lightens (sanguineous, serosanguinous, then serous) or the amount of output decreases.

Collecting a Wound Culture

If assessment of the wound indicates a possible infection, it is important to culture the wound. Culturing the wound allows identification of the infecting organism(s) and appropriate interventions. Skill 33-6 on pages 1220–1224 reviews the process for obtaining a wound culture.

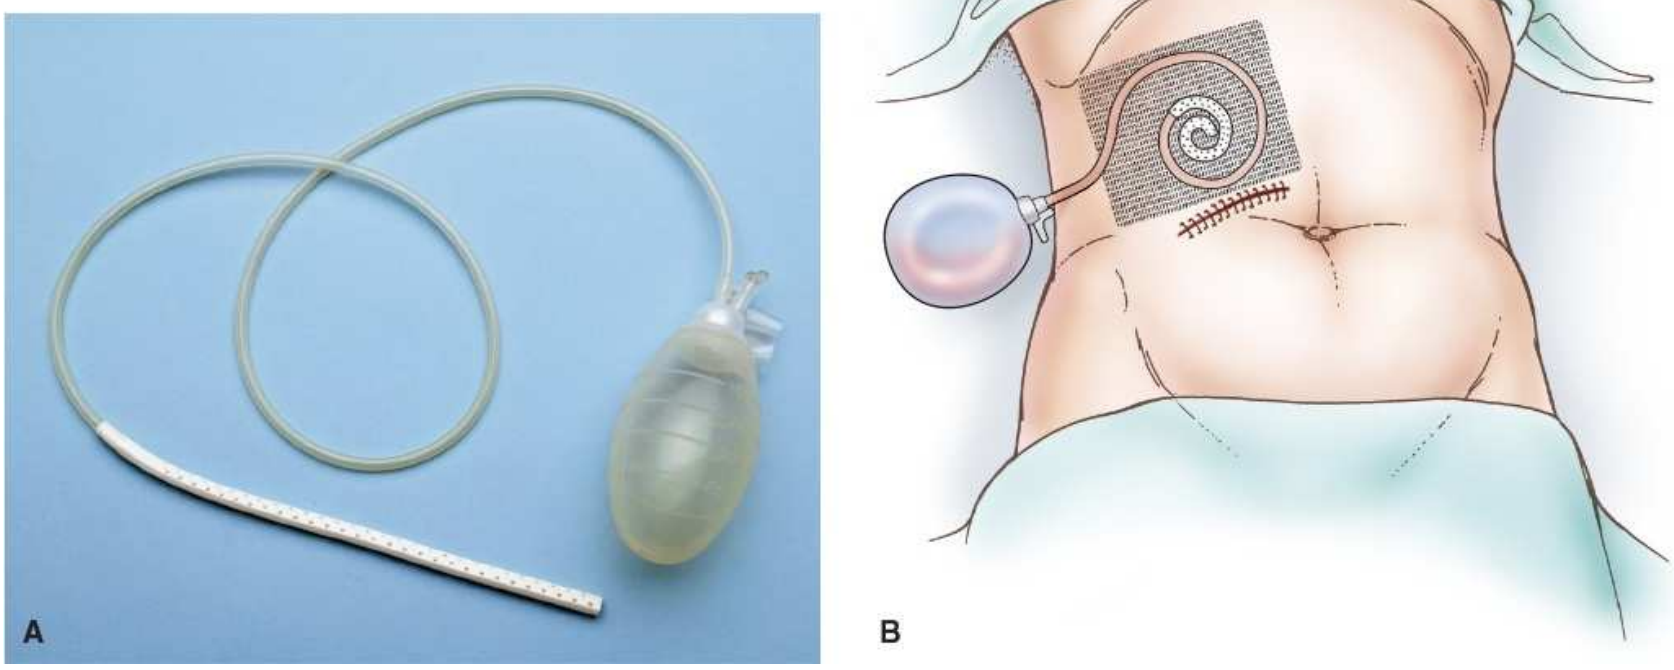

FIGURE 33-15. (**A**) Jackson-Pratt drain; (**B**) Jackson-Pratt drain inserted, with bulb compressed, which provides suction.

Using Additional Techniques to Promote Wound Healing

FIBRIN SEALANTS

Fibrin sealants are comprised of two substances found naturally in the human body: fibrinogen (a protein) and thrombin (an enzyme that acts on the fibrinogen to create a fibrin clot). Sealants are available in sponges, patches, and bandages; the glue is a liquid form that is applied using a gun or aerosol spray, which must be used per the manufacturer recommendations to prevent the introduction of an air or gas embolism (Edwards et al., 2016). The sealant is applied to tissues during an operative procedure to stop bleeding and glue together epidermal surfaces. This allows for wound closure with minimal drainage or scarring. The fibrin sealants have been shown to decrease the risk of hematoma (blood), decrease seroma (serous fluid) formation, and decrease the need for blood transfusion in some surgeries, but more research needs to be done on this topic (Daud et al., 2020; Edwards et al., 2016; Sircana et al., 2020). The glue is eventually metabolized and absorbed by the body. Dressings are not needed over these wounds because the skin is closed completely.

NEGATIVE PRESSURE WOUND THERAPY

Negative pressure wound therapy (NPWT) promotes wound healing and wound closure through the application of uniform negative pressure on the wound bed, reduction in bacteria in the wound, and the removal of excess wound fluid, while providing a moist wound healing environment. In clinical practice, this device is commonly referred to as a *wound V.A.C.* (vacuum-assisted closure) after one of the first devices approved by the U.S. Food and Drug Administration in 1995 (Hurd et al., 2017). The negative pressure results in mechanical tension on the wound tissues, stimulating cell proliferation, blood flow to wounds, and the growth of new blood vessels. There is some evidence that NPWT results in fewer surgical site infections for people experiencing primary wound closure, but until further evidence is published, the efficacy of NPWT with this type of wound remains uncertain (Norman et al., 2020). The device typically requires a foam interface (in the wound) covered by a thin, transparent or hydrocolloid dressing that is connected to a plastic tube attached to a suction mechanism (Baranoski & Ayello, 2020). It is used to treat a variety of acute or chronic wounds, wounds with heavy drainage, wounds failing to heal, or wounds healing slowly. Examples of such wounds include stage 3 or stage 4 pressure injuries (EPUAP, NPIAP, & PPPIA, 2019b); arterial, venous, and diabetic ulcers; dehisced surgical wounds; infected wounds; skin graft sites; and full-thickness burns. NPWT is not considered for use in the presence of active bleeding; wounds with exposed blood vessels, organs, or nerves; malignancy in wound tissue; presence of dry/necrotic tissue; wounds with exposed vessels, nerves, tendons and ligaments; allergy to any component; or with fistulas of unknown origin (Baranoski & Ayello, 2020; Hurd et al., 2017). Assess candidates for preexisting bleeding disorders or the use of anticoagulants and other medications or supplements that prolong bleeding times (Baranoski & Ayello, 2020). Skill 33-7 on pages 1224–1229 outlines the procedure for applying NPWT.

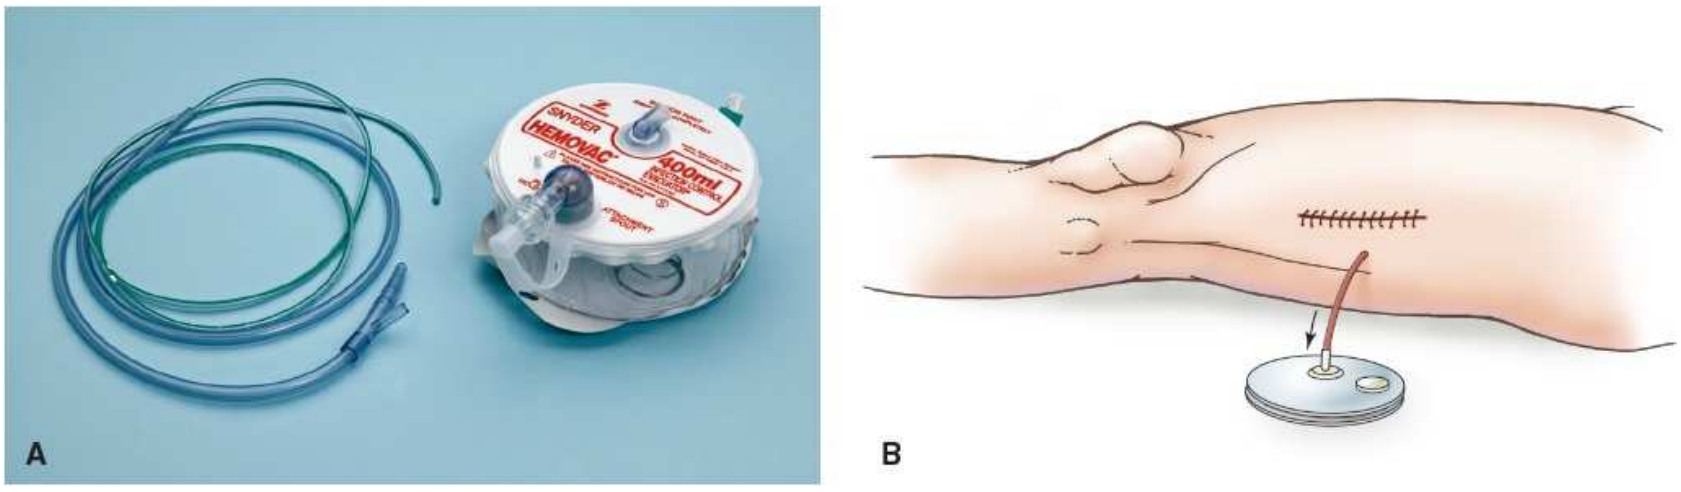

FIGURE 33-16. (**A**) Hemovac drain; (**B**) Hemovac drain inserted, with device compressed, which provides suction.

GROWTH FACTORS

Growth factors are naturally occurring proteins. Recombinant platelet-derived growth factor (PDGF) is the only exogenous (introduced from outside the body) growth factor that has shown to be effective in wounds with delayed healing (EPUAP, NPIAP, & PPPIA, 2019b). PDGF activates the immune cells and fibroblasts and promotes the formation of the extracellular matrix (Baranoski & Ayello, 2020; Han & Ceilley, 2017).

HYPERBARIC OXYGEN THERAPY

Hyperbaric oxygen therapy (HBOT) is an advanced wound care technology used to facilitate repair of chronic wounds that occur secondary to diabetes, arterial or venous vascular issue, or pressure injury. These wounds are typically characterized by a lack of oxygen (hypoxia), impaired ability to generate new blood vessels (angiogenesis), and prolonged inflammation (Hajhosseini et al., 2020). HBOT involves placing patients in a hyperbaric, pressurized chamber, where they breathe 100% oxygen, which greatly increases the amount of oxygen dissolved in the plasma. The tissues are exposed to the high-concentration oxygen environment, which promotes cell proliferation and healing, increases wound metabolism, promotes an increased response to growth factors, stimulates angiogenesis, and has antibacterial and antioxidant effects that improve immune function (Baranoski & Ayello, 2020; Han & Ceilley, 2017). Based on a mix of evidence in the literature, the cost of this therapy, potential knowledge deficits related to inconsistent implementation, and a lack of high-quality studies (Hajhosseini et al., 2020), the use of HBOT as an adjunctive therapy is considered on a case-by-case basis.

HEAT AND COLD THERAPY

The application of heat or cold is sometimes used as part of the treatment of wounds. The application of heat accelerates the inflammatory response to promote healing. The local application of cold constricts peripheral blood vessels, reduces muscle spasms, and promotes comfort. The use of these therapies is discussed later in the chapter.

OTHER TREATMENT OPTIONS

When other treatment options have failed, surgery may be considered. Surgical procedures may include debridement, direct closure of the wound, skin grafting, various skin flap procedures, or limb amputation. The decision is based on the patient's condition and the severity of the wound or pressure injury. After surgery, vigilantly protect the surgical site from pressure and contamination.

Several other treatment modalities are being investigated. They include electrical stimulation, light therapy, ultrasonic energy, pulsed lavage, and miscellaneous topical agents (such as topical oxygen therapy) and systemic drugs (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019b).

Removing Sutures or Staples

Sutures are removed when the wound has developed enough tensile strength to hold the wound edges together during healing. This stage varies from patient to patient, depending on age, nutritional status, and wound location. Silk sutures typically are removed within 6 to 8 days to prevent suture marks, even though collagen formation and remodeling take a total of at least 21 days. This means the scar may still stretch and widen after the silk sutures have been removed. Special subcutaneous techniques have been developed to minimize this problem.

Sutures are removed with a suture removal set; staples are removed with a special staple remover. The steps in removing sutures and staples are summarized in the accompanying Guidelines for Nursing Care 33-5 on page 1190. After the removal of skin sutures, small adhesive wound-closure strips that look something like tape are sometimes applied across the healing wound to help hold it together and give additional support as it continues to heal (Fig. 33-17). Unless otherwise directed, these adhesive strips are not removed during wound care.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 33-17. Applying Steri-Strips on an incision.

Guidelines for Nursing Care 33-5

Removing Staples and Sutures

The removal of staples or sutures may be done by the physician, an advanced practice professional, or by the nurse with a prescription/order. Always follow facility protocol; keep in mind these general guidelines:

- Use sterile technique, following recommended CDC guidelines for care of wounds.
  - Perform hand hygiene before and after the procedure.
  - Explain the procedure to the patient. Describe the sensation that will be experienced as a pulling or pinching.
  - Use proper technique to remove and dispose of old dressings.
- Clean the incision from the center of the wound outward, per facility policy and procedure for type of agent.
- Remove every other suture or staple to be sure wound edges are healed; if they are, remove remaining sutures or staples as ordered.
- Remove or reapply dressing, depending on health care provider preference and facility policy.
- Butterfly closure (Steri-Strip) application may be ordered for the healed wound after removal of staples or sutures to give additional support to the wound as it continues to heal. Follow facility protocol and primary care provider preference for placement of these tapes.

Figure A. Removing sutures.

Specifics for Suture Removal

1. Use a sterile suture removal kit.

2. Using the sterile forceps, grasp the knot of the first suture and gently lift the knot.
3. Using the sterile scissors, cut one side of the suture below the knot close to the skin (Figure A).
4. Grasp the knot with the forceps and pull the cut suture through the skin (be sure to pull through the healed wound only the portion of the suture that has been inside the tissue).

Specifics for Staple Removal

1. As directed on the package, gently position the sterile staple remover under the staple to be removed.
2. Firmly close the staple remover to straighten the staple ends; do not lift upward while disengaging staple ends (Figure B).
3. Carefully lift upward with the closed staple remover to remove the staple from the incision line. It may be necessary to remove one end of the staple and then the other if it does not easily lift out.

Figure B. Firmly closing the staple remover, bending the staple in the middle, and pulling the edges out of the skin.

Teaching Wound Care at Home

GENERAL GUIDELINES

With the increase in ambulatory surgery and earlier discharge of patients from inpatient settings to home care, teaching patients and their families about wound care is important. Although a nurse may be needed to change dressings and provide wound care in complex situations, caregivers often are taught how to perform the procedure. To provide the continuity of care that is necessary to prevent infection and promote healing, be sure to include teaching about wound care as part of discharge planning and in interactions with home care patients and caregivers. A summary of teaching content is outlined in Teaching Tips 33-1: Wound Care and Healing.

PRESSURE INJURY PREVENTION AND CARE

Teaching patients and caregivers how to prevent pressure injury requires a comprehensive, organized educational effort. Initially, the health care provider presents basic information that explains the terminology, identifies risk factors, explains where and how pressure injuries develop, and describes various prevention strategies and options. Illustrated instructions written at the level of the learner are a valuable resource. The protocols listed in the Guidelines for Nursing Care boxes serve as a model for development of a teaching plan that incorporates basic principles and targets people at risk. As new information becomes available, education for prevention of pressure injury requires updating.

Teaching Tips 33-1

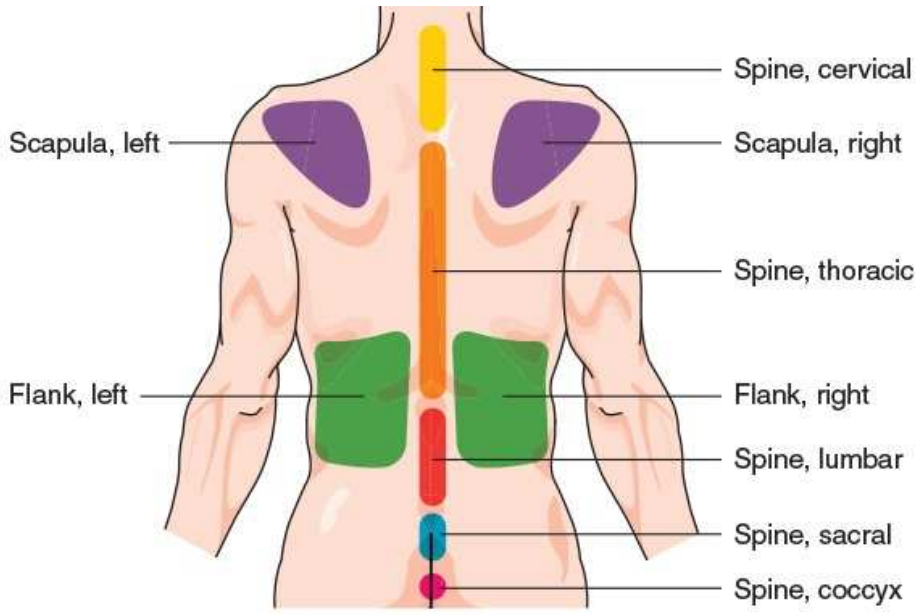
WOUND CARE AND HEALING

Health Topic	Teaching Tip	Why Is This Important?
Supplies	• Methods for obtaining dressing supplies such as purchasing from pharmacies, drug stores, discount stores, and medical supply stores	Patients need to be able to obtain appropriate supplies to perform prescribed care. Wound care will not be completed if supplies cannot be obtained for financial

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	• Considerations of costs and ease of use • Investigation about reimbursement by insurance or other source of health care financing	or other reasons, the wound care is complex, or the patient does not understand the wound care instructions.
Infection prevention	• Signs and symptoms of infection to be immediately reported to the health care provider • Need to watch for increased body temperature, flulike symptoms, red or separated wound edges, increased pain in the wound, and/or increased drainage that is thick and has a foul odor • Hand hygiene before putting on and after removing disposable gloves • Proper methods for disposal of old dressing, such as wrapping old dressing the used glove or in several layers of newspaper before putting it in a plastic bag for disposal in a trash container	Early detection of possible complications promotes early intervention and prevention of further complications. Preventative measures reduce transmission of microorganisms.
Wound healing	• Importance of eating well-balanced meals that are high in protein and vitamins • Need to drink six to eight glasses of fluids each day • Rest periods during the day • Modifications in activities of daily living and exercise until healing is complete and the health care provider recommends a return to regular activity	Promoting wound healing is essential.

Involve the patient and caregivers in the plan of care and provide them with a good understanding about causative factors for the pressure injury. Instruct them in proper hand hygiene techniques and how to identify the signs and symptoms of infection. Provide the patient and caregivers with simple, easy-to-read instructions. Encourage frequent consultation with the primary health care provider about the progress of wound healing and products used. In addition, ensure that the patient, family, or caregivers understand the need for adequate nutrition to aid in wound healing. Assess the patient's nutritional status and suggest consultation with a dietitian for dietary deficiencies, if necessary.



If dressing changes or wound care is painful, teach the patient to use pain medication as prescribed 30 to 45 minutes before the procedure. Reinforce the importance of hand hygiene before and after the dressing change.

Documenting Wound Care

Documentation related to wound care is an important nursing responsibility. Clear and accurate documentation is essential for communicating wound status and tracking the progression of healing. Precise documentation contributes to continuity of care, accurate evaluation of care, and appropriate changes in wound care, if necessary. Photographs of a wound contribute to accurate assessment documentation and measurement of changes over time. Figure 33-18 on page 1192 shows an example of an electronic documentation tool. Comprehensive wound documentation includes the following elements (Baranoski & Ayello, 2020):

- Any change in clinical status or wound healing
- Characteristics of the wound (see Fig. 33-18 on page 1192)
- Wound care and dressing(s)
- Nutritional status
- Support surfaces in use (bed and chair) and repositioning schedule
- Regular, scheduled reassessment of the wound

- Routine daily skin assessment and care using a standardized instrument
- Any other required forms for reimbursement

Region:	Back	**Description:**	Open stage 2 pressure injury 2 cm x 2 cm x .5 cm, with partial-thickness skin loss and exposed dermis; dark red edges, pink interior, and small amount of serosanguineous drainage.
Specific location:	Spine, sacral		
Type:	Pressure injury, stage 2	**Peri-wound area:**	Stage 1 pressure injury surrounding ulcer: 5 cm x 6 cm area of non-blanchable erythema; reddened, but intact.
Length:	2	**Dressing and wound care:**	Irrigated wound and with normal saline and applied hydrocolloid dressing per prescription to sacrum.
Width:	2	**Focused notes:**	Patient reported pain 1/10 during assessment and dressing change; tolerated procedure without incident. Plan to ensure dressing remains intact and change every 3–7 days as needed.
Depth:	.5		

FIGURE 33-18. Electronic wound and skin assessment/documentation example from a web-based academic EHR simulation.

Evaluating

Evaluation of wound and pressure injury care involves reassessment at regular intervals to monitor response to the treatment, determine the effectiveness of the treatment, and allow for necessary changes in the plan of care. When evaluating the effectiveness of a plan of care designed to prevent the development of pressure injuries or to treat pressure injuries or other wounds already present, the nurse uses each nurse–patient interaction to determine if the patient has met the individualized expected outcomes. Nursing care is considered effective if the patient, family member, or caregiver expresses satisfaction with prevention and treatment measures and can accomplish the following:

- Participate effectively in preventive and treatment regimens
- Prevent development of any additional areas of skin breakdown
- Demonstrate progressive healing of pressure injury or other wound
- Improve overall physical condition (including nutritional state and mobility status)
- Remain free of infection at any pressure injury or other wound site
- Communicate the need for additional support (environmental, physical, psychosocial)

Evaluation is a continuous process that involves ongoing assessment and revised plans and implementations. Color photographs are an excellent method of objectively evaluating the progression of wound healing, allowing visual comparison of the wound at the initial assessment and throughout the treatment and recovery stages.

HEAT AND COLD THERAPY

Heat and cold are applied to a specific part or all of a patient's body to bring about a local or systemic change in body temperature for various therapeutic purposes. Physiologic responses to heat and cold are modified by the method and duration of application, the degree of heat and cold applied, the patient's age and physical condition, and the amount of body surface covered by the application. Nurses use heat and cold as nursing interventions in both hospital- and community-based settings.

Body temperature is regulated by cells in the hypothalamus in response to signals from thermal (heat and cold) receptors located close to the skin's surface. Stimulation of these receptors sends sensory messages to the anterior hypothalamus to initiate mechanisms to dissipate heat (through vasodilation and sweating) or to preserve warmth

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

through vasoconstriction and piloerection (*goose bumps*). Pain receptors, also located near the skin's surface, are also affected by heat and cold as painful stimuli, with excessive heat perceived as burning and excessive cold experienced as numbness followed by pain.

Effects of Applying Heat

The application of local heat dilates peripheral blood vessels, increases tissue metabolism, reduces blood viscosity, increases capillary permeability, reduces muscle tension, and helps relieve pain. Vasodilation increases local blood flow. In turn, the supply of oxygen and nutrients to the area is increased, and venous congestion is decreased. As local blood flow increases, the viscosity of blood is reduced. Increased capillary permeability improves the delivery of leukocytes and nutrients, while also facilitating the removal of wastes and prolonging clotting time. These actions, combined with increased tissue metabolism, accelerate the inflammatory response to promote healing.

Heat reduces muscle tension to promote relaxation and helps to relieve muscle spasms and joint stiffness. Heat also helps relieve pain by stimulating specific nerve fibers, closing the gate that allows the transmission of pain stimuli to centers in the brain. Because of these local physiologic effects, heat in various forms is used to treat infections, surgical wounds, inflamed tissue, arthritis, joint and muscle pain, dysmenorrhea, and chronic pain.

The systemic effects of extensive, prolonged heat include increased cardiac output, sweating, increased pulse rate, and decreased blood pressure. This response occurs when heat is applied to a large body area, increasing the blood flow to that area while decreasing it to another part of the body, in effect, causing hypovolemic shock.

Effects of Applying Cold

The local application of cold constricts peripheral blood vessels, reduces muscle spasms, and promotes comfort. Cold reduces blood flow to tissues and decreases the local release of pain-producing substances such as histamine, serotonin, and bradykinin. This action in turn reduces the formation of edema and inflammation. Decreased metabolic needs and capillary permeability, combined with increased coagulation of blood at the wound site, facilitate the control of bleeding and reduce edema formation.

Cold also reduces muscle spasm, alters tissue sensitivity (producing numbness), and promotes comfort by slowing the transmission of pain stimuli. Cold, for these effects, is used after direct trauma, for dental pain, for muscle spasms, after sprains, and to treat some chronic pain syndromes.

Exposure to prolonged or extensive environmental cold produces systemic effects of increased blood pressure, shivering, and goose bumps. Although shivering is a normal body response to cold, prolonged exposure to cold temperatures may cause tissue injury.

Physiologic Considerations

The rebound phenomenon is important to the therapeutic value of heat and cold and to the safety of patients receiving such therapy. Heat produces maximum vasodilation in 20 to 30 minutes; if heat is continued beyond that time, tissue congestion and vasoconstriction occur (for unknown reasons). With cold, maximum vasoconstriction occurs when the skin reaches 60°F (15°C); then vasodilation begins.

The ability of the body to adapt to heat and cold is an important consideration when applying heat or cold and when teaching patients and caregivers about heat and cold therapy. Initially, heat and cold skin receptors are stimulated strongly by sudden changes in temperature. For the first few seconds after being stimulated, the response decreases rapidly. It then decreases more slowly for the next 30 minutes, as the receptors adapt to the temperature. A hot application, even if the temperature remains constant, does not feel as warm after adaptation has taken place. Be sure to inform patients that increasing the temperature or lengthening the time of application can seriously damage tissues.

NURSING PROCESS FOR HEAT AND COLD THERAPY

Assessing

Before initiating heat or cold therapy, assess the patient's physical and mental status, the condition of the body area to be treated with heat or cold, and the condition of the equipment to be used. Carefully evaluate factors influencing the patient's ability to tolerate heat and cold applications. These factors are the basis for the following considerations:

- How long will the heat or cold be applied? Prolonged exposure increases tolerance, and rebound effects are undesirable.
- What body part is involved? Some body areas, such as the neck, perineum, and inner aspects of the wrist and forearm, are more sensitive to thermal changes.
- Is the skin intact? Open tissue or abraded skin is more sensitive to thermal changes.
- How large is the area? Applications of heat or cold to large areas of the body cause systemic responses and lower tolerance of temperature change.

- What is the patient's age? Infants, children, and older adults do not tolerate temperature changes as well as adults.
- What is the patient's physical condition? Patients with certain alterations in health, such as those with cardiovascular or peripheral vascular diseases, might have reduced response to or tolerance of thermal changes.

Assessing Overall Status

Assessing the patient's overall status includes obtaining a health history and completing a physical examination. A history of cardiovascular or peripheral vascular impairment, sensory impairment, and alterations in mental status, such as confusion or decreased level of consciousness, indicates the need for caution when using heat or cold because of the danger of tissue damage. Assessments include response to stimuli (sharp and dull), color and appearance of body tissues, circulation (pulses, blanching sign, temperature, color), level of consciousness, and orientation.

Consider **Mr. Everly**, the postoperative patient in the critical care unit. Imagine that the provider had prescribed heat or cold applications for this patient. The nurse would need to obtain a thorough assessment of his physical status when planning this care. His history of diabetes and circulation problems, coupled with his decreased level of consciousness, would place him at high risk for injury and tissue damage. In addition, the nurse would need to assess him frequently during the application of heat or cold to ensure his safety.

Do not apply heat to an open wound immediately after the trauma; during hemorrhage; over noninflammatory edema; to an acutely inflamed area, a localized malignant tumor, the testes, or the abdomen of a pregnant woman; or over metallic implants. Conversely, do not use cold for open wounds or for patients with impaired peripheral circulation or adverse reactions to cold.

Assessing the Area of Application

Perform baseline assessments to ensure safety and to evaluate the outcomes of therapy. The risk for damage to tissues is increased if the area is traumatized or has altered integrity. Assess for open lesions, blisters, wounds, edema, bleeding, or drainage. Also look for evidence of altered circulation such as changes in color, temperature, pulses, and sensation. As with any assessment, compare body parts bilaterally for changes. Tissues with decreased or absent pulses, those that appear pale or cyanotic, and those that feel cold to the touch indicate a decrease in circulation. Subsequently, the risk for injury from heat and cold applications increases.

When the heat or cold is applied, make ongoing assessments to ensure patient safety and comfort. When heat is applied, assess the patient for undesired responses, including localized redness, blistering, and pain (symptoms of burning), along with possible systemic responses, such as hypotension and changes in consciousness. When cold is applied, assess for localized responses, including pallor, cyanosis, numbness, and pain.

Assessing the Condition of Equipment

The nurse is responsible for checking the equipment used and for maintaining patient safety. Included in this responsibility is checking the condition of cords, plugs, and heating or cooling elements. In addition, inspect the equipment for fluid leaks. Also, check to ensure that the equipment distributes and maintains the constant temperature. Do not use faulty equipment; if faulty equipment is found, it should be returned for repair.

Diagnosing

The patient's need for and response to the heat or cold suggest possible nursing problems or needs, including the following:

- Acute or Chronic pain
- Altered tissue perfusion
- Thermal injury risk

Outcome Identification and Planning

Heat and cold are used for a variety of therapeutic purposes. When applications of heat or cold are part of a plan of care, the following outcomes are appropriate; specific outcomes should be chosen based on the purpose of the application. The patient will:

- Verbalize increased comfort

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Demonstrate evidence of wound healing, decreased muscle spasms, decreased edema, and increased comfort
- Verbalize and demonstrate safe hot or cold application

Implementing

Heat and cold applications may be moist or dry, using many forms and methods. The prescription for the heat and cold application should include the type of application, the body area to be treated, the frequency recommended, and length of time for the applications.

Explain to the patient the purpose and steps of the application and the sensations that will be experienced. In the hospital, provide a timer or clock and have the call bell within reach. In the home, teach the patient or caregiver to check the equipment each time to ensure that it is in good working order, avoid lying or leaning on the equipment, cover the heating device with a protective cloth, apply heat only for the prescribed time period, and report any changes in sensation or discomfort to the health care provider.

Applying Heat

Heat is applied by both dry and moist methods. Hot water bags, electric heating pads, aquathermia pads, or chemical heat packs provide local dry heat by conduction. Hot compresses or packs, sitz baths, or soaks provide moist heat by conduction.

DRY HEAT

Hot Water Bags

Hot water bags are a method of dry heat application. Although relatively easy and inexpensive to use, they have disadvantages. They may leak, and often the weight of the bag or bottle on the patient's body part can be uncomfortable. Moreover, there is a danger of burns from improper use.

Electric Heating Pads

An electric heating pad can be used to apply dry heat locally. It is easy to apply, is relatively safe to use, and provides constant and even heat. Improper use can, however, result in injury. When applying a heating pad, follow manufacturer-specific and these general recommendations:

- Avoid using pins to secure a heating pad. There is a danger of electric shock if a pin touches a wire.
- Place a covering over the pad, preferably one that is moisture proof. Also, prevent wet and moist conditions around the pad. Short-circuiting the heating element may cause an electric shock. Do not cover the heating pad with anything that might be heavy; heat may accumulate and burn the patient when it cannot dissipate normally from the pad.
- Place a heating pad anteriorly or laterally to, not under, the body part. If the heating pad is between the patient and the mattress, heat dissipation may be inadequate, leading to burning of the patient or the bed linens.
- Use a heating pad with a selector switch that cannot be turned up beyond a safe temperature. After the patient's receptors adapt to the initial application of heat, the patient may attempt to inappropriately increase the heat. Many people have been burned by turning up the heat in an electric pad because they thought the pad was too cool.
- Assess the skin at regular intervals for the effects of excessive exposure to heat such as increased skin redness, changes in sensation, or discomfort.
- Check facility protocol for the use of heating pads; a release form may need to be signed.

Aquathermia Pads

Aquathermia (Aqua-K) pads are commonly used in health care facilities and homes for various health problems, including back pain, muscle spasms, thrombophlebitis, and mild inflammation. These devices are safer to use than a heating pad, but they too must be checked carefully. Guidelines for using an aquathermia pad are given in Skill 33-8 on pages 1230–1232.

Hot Packs

Commercial hot packs provide a specified amount of dry heat for a specific period. Instructions on the package describe how to activate the pack, either by striking it on a firm surface, or by squeezing or kneading it. Follow the same precautions as for other types of dry heat applications.

MOIST HEAT

Warm Moist Compresses

Warm moist compresses are used to promote circulation and healing, and to reduce edema. Because moist heat evaporates and cools rapidly, change these compresses frequently and cover them with a heating agent (hot water bottle, heating pad, Aqua-K pad).

Sitz Baths

Sitz baths are a method of applying tepid or warm water to the pelvic, perineal, or rectal areas by sitting in a tub, special chair, or basin filled with sufficient water to reach the umbilicus. Special basins that fit onto the toilet seat are available. They are designed so that the patient's buttocks fit into a rather deep seat that is filled with water of the desired temperature; the legs and feet remain out of the water. The basins are disposable and economical for home or health care facility use. A regular bathtub is not as satisfactory for a sitz bath because the heat causes generalized vasodilation, altering the effect desired. Techniques for administering a sitz bath are given in Guidelines for Nursing Care 33-6 on page 1196.

Warm Soaks

The immersion of a body area into warm water or a medicated solution is called a soak. The purposes of soaks vary: to increase blood supply to a locally infected area; to aid in cleaning large, sloughing wounds, such as burns; to improve circulation; and to apply medication to a locally infected area. A soak has the added advantage of making manipulation of a painful area much easier because the body part is buoyed by the weight of water it displaces. Hydrotherapy, such as pulsatile lavage with suction, may be used to promote wound cleaning and debridement in pressure injuries (EPUAP, NPIAP, & PPPIA, 2019b). If a warm soak is prescribed, follow these general guidelines:

- If a soak is prescribed for a large wound (e.g., an entire arm or lower leg or even an area of the torso), expect to adapt sterile technique. For example, sterilize the container into which the body area is placed before use if possible; if not, clean the container scrupulously. Tap water may be used for soaks because it is accepted as being free from pathogens.
- Unless the temperature of the soak is prescribed otherwise, set the temperature of the water within a range of 105° to 109°F (40.5° to 43°C), which is considered to be physiologically effective and comfortable for the patient.
- Position the container holding the fluid so that the part to be immersed is comfortable and the patient is in good body alignment.
- During the treatment, which usually takes 15 to 20 minutes per soak, maintain the temperature of the soak as constant as possible. This may be done by discarding some of the fluid every 5 minutes and replacing it or by adding solutions at a higher temperature while agitating the water. When replacing or adding fluids, have the patient remove the extremity from the soak.

Applying Cold

Cold is applied by both dry and moist methods. Dry cold is provided with ice bags, cold packs, or a hypothermia blanket (or pad). Cold compresses are a method of applying moist cold.

DRY COLD

Ice Bags

An ice bag, like its counterpart the hot water bottle or bag, is a relatively easy and inexpensive method for applying cold to an area. It has essentially the same disadvantages as the hot water bag. Placing ice bags in the axilla, neck, and groin regions effectively lower the patient's core temperature quickly and are used when therapeutic hypothermia (32°C to 36°C) is indicated. When using an ice bag, follow these recommendations:

- Fill the bag with small pieces of ice to about two thirds full. This makes the bag lightweight. Using ice chips, rather than cubes, makes it easier to mold the bag to the body part.

Guidelines for Nursing Care 33-6

ASSISTING WITH A SITZ BATH

- Test the water in a sitz bath (Figure) with a thermometer before the patient enters the water.
- If the purpose of the sitz bath is to apply heat, use water at a temperature of 34° to 37°C (93° to 99°F) for 15 minutes to produce relaxation of the parts involved after a short initial period of contraction. Do not use warm water if considerable congestion is already present.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Sitz bath

- If the purpose of the sitz bath is to produce relaxation or to promote healing in a wound by cleansing it of discharge and debris, use water at a temperature of 34° to 37°C (93° to 99°F). Check facility protocols for the correct temperature.
- Assist the patient into the tub or onto the sitz bath and position properly. The patient should be able to sit in the basin or tub with the feet flat on the floor without any pressure on the sacrum or thighs.
- Wrap a blanket around the shoulders to protect from chilling and exposure.
- Monitor the patient closely for signs of weakness and fatigue, and discontinue the bath if faintness, pallor, a rapid pulse rate, or nausea is noted.
- Test the water in the tub several times and keep it at the desired temperature. Additional hot water may be added by pouring it slowly from a pitcher or by opening the hot water faucet slightly. Agitate the water by stirring it as the hot water is added to prevent burning the patient.
- Do not leave the patient alone if there are any questions about safety.
- Help the patient out of the tub when the bath is completed. A sitz bath should take 15 to 20 minutes. Help the patient dry and cover them adequately.

- Remove air from the ice bag in the same manner as removing air from a hot water bag.
- After securing the cap, test the ice bag for leaks and wipe off excess moisture.
- Place a cover on the ice bag to provide comfort and to absorb moisture that may accumulate on the outside of the bag.
- Apply an ice bag for 15 to 20 minutes, then remove it for about an hour before reapplying it. This technique prevents the effects of prolonged exposure to cold (Fig. 33-19).
- In the home setting, a bag of frozen vegetables (such as peas) makes a good substitute for an ice bag.

Cold Packs

Commercially prepared ice packs are available in many health care facilities and may be purchased for home use. These bags are sealed containers filled with a chemical or a nontoxic substance. Depending on the type, the bags are frozen in the freezer or (if not frozen) are squeezed to activate the chemical that produces the cold. These packs are advantageous because the frozen solution remains pliable and can be easily molded to fit the body part. They are covered with a ribbed cotton sleeve so that the bag can be slipped onto an extremity, or the bag can simply be placed on a body part, such as the head. Assess the skin beneath the pack periodically for symptoms of numbness and pain.

FIGURE 33-19. Cloth-wrapped ice bag. (*Source:* Reprinted with permission from Craven, R. F., Hirnle, C. J., & Henshaw, C. M. [2017]. Fundamentals of nursing: Human health and function [8th ed.]. Wolters Kluwer Health.)

MOIST COLD

Moist, cold local applications are called cold compresses. They might be used for an injured eye, a headache, a tooth extraction, and sometimes for hemorrhoids. The texture and thickness of the material used depend on the area to which it is applied. For example, eye compresses could be prepared from surgical gauze compresses, which have a small amount of cotton filling. A washcloth makes an excellent compress for the head or face.

Immerse the material used for the application in a clean basin that contains pieces of ice and a small amount of water. Wring the compress thoroughly before applying it to avoid dripping. Dripping is uncomfortable for the patient and may result in wetting the patient's clothing or bed linens. Change the compress frequently, continuing the application for 20 minutes. Repeat the application every 2 to 3 hours as ordered. Ice bags or commercial devices are available for keeping the compresses cold, helping to decrease the frequency with which they must be changed.

Evaluating

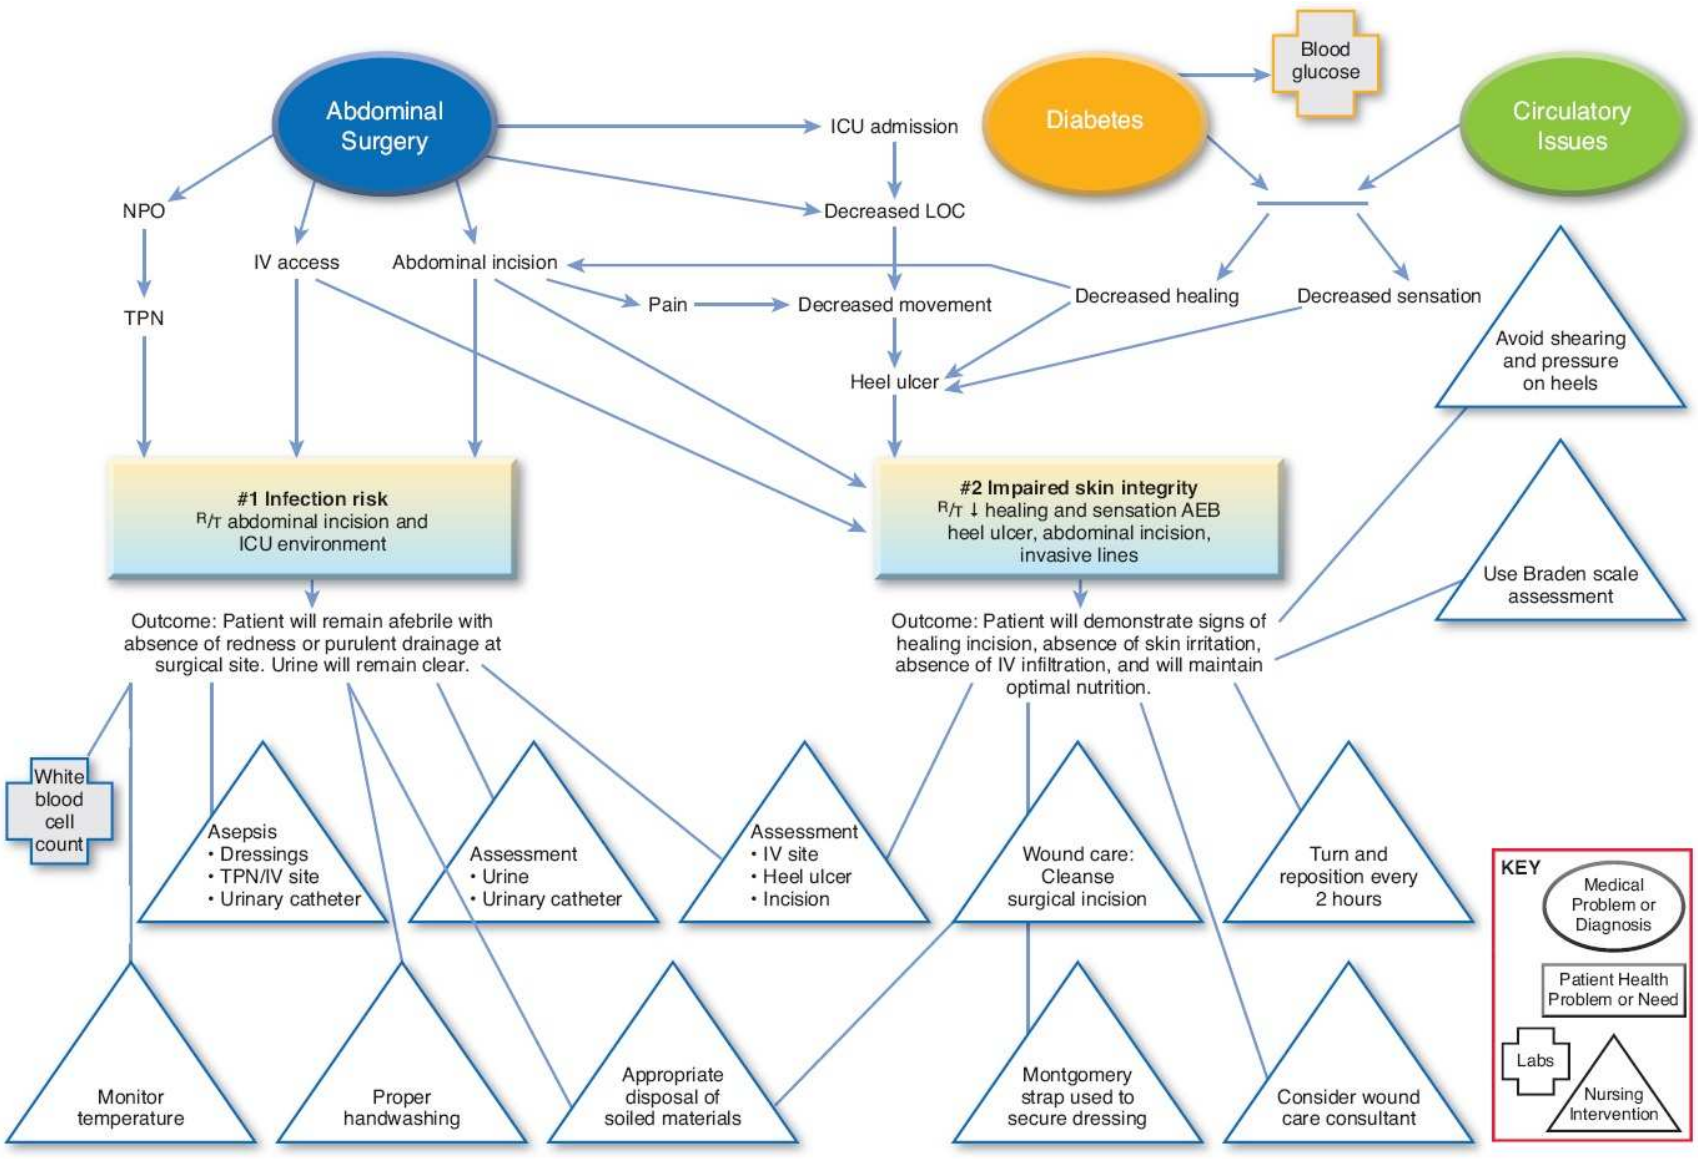
The expected outcomes for applying heat and cold are used to evaluate the effectiveness of the planned interventions. Although the specific outcomes depend on the purpose of the application, nursing care is considered effective if the patient is able to:

- Verbalize increased comfort
- Verbalize increased ability to rest and sleep
- Demonstrate evidence of wound healing
- Demonstrate a decrease in symptoms of muscle spasms, inflammation, and edema
- Verbalize and demonstrate safe hot and cold applications

Ongoing evaluation of skin integrity is needed to determine needs and the effectiveness of any interventions, including heat and cold therapy. (See the accompanying concept map for Lucius Everly and the Evolving Case Study for Sam Bentz, on pages 1233–1234.)

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the object of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop your expertise in evaluating the plan of care, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following:



- How aware are you of current initiatives to prevent the development of pressure injuries? What are some standard practices across the health care continuum designed to promote skin integrity in your at-risk patients?
- What value do you attach to involving and empowering the patient throughout the wound care process? How do you individualize the care for patients when so many guidelines, policies, and procedures dictate your care? How will you

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

identify the resources, equipment, and supplies necessary to provide safe, quality wound care for your patient?
- What plan do you have to stay abreast of evolving standards and wound care procedures? What are the core principles of preventative skin care that will exist irrespective of evolving technologies?

Keeping up with the latest evidence-based practice guidelines can be challenging. Ensuring you are tuned into the appropriate professional organizations and governmental facilities can help you stay on the cutting edge. Balancing the needs of each patient with these responsibilities requires mindfulness and intentionality.

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to ensure appropriate skin and wound care? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Evaluation
- **Diagnosis #1** Lucius is afebrile, urine is clear, no drainage noted from heel ulcer, serosanguineous drainage from incision. Continue interventions.
- **Diagnosis #2** Lucius has dressing changes done per protocol. Pink granulation tissue noted at surgical incision, no skin irritation. IV sites intact, TPN infusing. Continue interventions.

Skill 33-1 Preventing Pressure Injury

DELEGATION CONSIDERATIONS

The assessment of a patient's skin is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, licensed practical/vocational nurses (LPN/LVNs) may perform some or all of the parts of assessment of the patient's skin. The use of interventions related to prevention of pressure injuries may be delegated to AP as well as to LPN/LVNs. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Pressure injury assessment form and/or risk assessment tool
- Functional assessment tool, as indicated
- Support surfaces, such as integrated bed systems, specialized and/or low-pressure mattresses and overlays, seating surfaces and cushions, heel elevation devices, and foam positioning wedges, as indicated
- Safe patient handling and movement devices, as indicated
- Protective dressings, such as polyurethane foam dressing, as indicated
- Low-friction patient care textiles, such as bed linens and patient gowns
- Personal hygiene and skin barrier products, as indicated
- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
 1. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 2. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
3. Discuss pressure injury prevention with the patient and/or patient family/caregivers. Explain what pressure injury is, the causes of pressure injuries, and the importance of a pressure injury prevention plan (McNichol et al., 2022).	These measures promote a collaborative relationship in which the patient is treated with respect. Explanation encourages patient understanding and reduces apprehension. Patient and caregiver education support engagement in care and assist patients to implement behaviors to meet goals for care (Joint Commission, 2018; Mitchell, 2018).
4. Assess the patient's skin at least daily, paying special attention to the skin over bony prominences and the skin in contact and under medical devices (Camacho-Del Rio, 2018; McNichol et al., 2022; EPUAP, NPIAP, & PPPIA, 2019a). Briefly assess the patient's skin at the pressure points during repositioning of the patient (EPUAP, NPIAP, & PPPIA, 2019a). Refer to Chapter 27 for additional skin assessment information.	Skin assessment provides information related to the patient's current status and detects impending or actual alterations in skin integrity (McNichol et al., 2022). Skin assessment provides information needed to develop an appropriate care plan. For patients at risk for pressure injury, the skin should be inspected as soon as possible upon admission to a health care service, as part of every pressure injury risk assessment, and additionally based on the individual's degree of pressure injury risk (EPUAP, NPIAP, & PPPIA, 2019a). Assessment of pressure points allows for identification of alterations in status and evaluation of the effectiveness of repositioning regimen; presence of persistent erythema may indicate the need to increase frequency of repositioning; pressure points

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	onto which the patient will be repositioned should appear fully recovered from previous loading (EPUAP, NPIAP, & PPPIA, 2019a).
5. Assess the patient's risk for pressure injury upon entry to a health care setting and on a regularly scheduled basis or when there is a significant change in the patient's condition, incorporating appropriate assessment tools and scales, based on facility policy (WOCN, 2016).	Risk for pressure injury development should be determined on admission, as often as required based on the patient's acuity and as a result of any change in the patient's status (EPUAP, NPIAP, & PPPIA, 2019a). Identification of people at risk for developing pressure injury is a critical component of prevention (Baranoski & Ayello, 2020).
6. Utilize appropriate support surfaces to redistribute tissue loads, both while in bed and when seated, based on individual patient assessment and needs, facility policy, and availability (Baranoski & Ayello, 2020; Haesler, 2018). Appropriate support surfaces may include, but are not limited to, integrated bed systems, specialized and/or low-pressure mattresses and overlays, seating surfaces and cushions, heel elevation devices, and foam positioning wedges. Note: Pressure redistribution devices should serve as adjuncts and not replacements for repositioning of patients (WOCN, 2016). **Do not use foam rings, foam cut-outs or donut-type devices.** The Wound, Ostomy and Continence Nurses Society (WOCN, 2016) has developed a content-validated algorithm for support surface selection. Refer to the General Considerations below.	Support surfaces help prevent pressure injury by redistributing pressure and manage tissue loads; sequentially altering the parts of the body that bear load (to reduce the duration of loading on individual anatomical sites); managing the microclimate (moisture and temperature control); and friction and shear control (Baranoski & Ayello, 2020; Kalowes, 2018). Support surfaces also provide for proper body alignment and comfort (Baranoski & Ayello, 2020). Foam rings, foam cut-outs or donut-type devices concentrate pressure on the surrounding tissue and should be avoided (WOCN, 2016).
7. Routinely reposition the patient: determine frequency with consideration to the patient's level of activity, physical, cognitive, and psychological condition; ability to independently reposition; the type of support surface in use; general health condition; patient comfort and pain (EPUAP, NPIAP, & PPPIA, 2019a; McNichol et al., 2022).	Repositioning reduces or relieves pressure and limits the amount of time tissues are exposed to pressure and contributes to the patient's functional abilities (EPUAP, NPIAP, & PPPIA, 2019a; McNichol et al., 2022; WOCN, 2016).
8. Implement early mobilization to increase the patient's activity and mobility as tolerated. Develop a schedule for progressive sitting and ambulation as rapidly as tolerated by the individual patient. Collaborate with the physical and occupational therapists to develop an individualized intervention plan. Refer to Chapter 34 for additional discussion related to early mobilization and ambulation of patients.	Mobilization and ambulation relieve pressure, contributes to the patient's functional abilities, and may reduce risk for deterioration related to prolonged immobility (EPUAP, NPIAP, & PPPIA, 2019). Early mobility plays an important role in the patient's physical and psychological well-being (Arnold et al., 2018). Physical and occupational therapists are important resources for maximizing patient mobility (Baranoski & Ayello, 2020).
9. Use a 20- to 30-degree side-lying position or flat in bed (if not contraindicated) when positioning patients at risk for pressure injury in side-lying positions (EPUAP, NPIAP, & PPPIA, 2019; WOCN, 2016).	Avoid lying positions that increase pressure, such as the 90-degree position (EPUAP, NPIAP, & PPPIA, 2019a).
10. Maintain the head-of-bed elevation at or below 30 degrees, or at the lowest degree of elevation appropriate for the patient's medical condition.	Head-of-bed elevation at or below 30 degrees prevents shear-related injury (WOCN, 2016).
11. Consider the use of a prophylactic (preventative) dressing, such as a polyurethane foam dressing, on bony prominences, such as heels, hips, and the sacrum (Kalowes, 2018). Assess skin under a prophylactic dressing at least daily; replace prophylactic dressings that are damaged, loosened, displaced, excessively moist, or if the dressing or	Prophylactic dressings reduce friction, pressure and shear, protect fragile skin, and influence microclimate (Cornish, 2017; Kalowes, 2018; Lovegrove et al., 2020; EPUAP, NPIAP, & PPPIA, 2019a; WOCN, 2016).

skin under the dressing becomes soiled and according to the manufacturer's directions (EPUAP, NPIAP, & PPPIA, 2019a).	
12. Consider the use of low-friction patient care textiles, such as bed linens and patient gowns. Refer to Chapter 34 for additional information related to safe patient handling and the use of patient handling and mobility devices.	Low-friction textiles reduce shear, minimize skin irritation and dry quickly (EPUAP, NPIAP, & PPPIA, 2019a; WOCN, 2016).
13. Utilize safe patient handling interventions when moving a patient. Collaborate with the physical and occupational therapists to develop an individualized intervention plan. Refer to Chapter 34 for additional information related to safe patient handling and the use of patient handling and mobility devices.	Proper lifting, positioning, and repositioning techniques are critical to prevent injury from shearing forces (McNichol et al., 2022). Physical and occupational therapists are important resources for maximizing patient mobility (Baranoski & Ayello, 2020).
14. Provide appropriate skin and personal hygiene (Kalowes, 2018; Mitchell, 2018; Yilmazer et al., 2019). Utilize interventions to protect the skin from excessive exposure to moisture from wound exudate, perspiration, mucous, saliva, fistula or stoma effluent, and urinary and fecal incontinence. Refer to Chapters 32, 38, and 39 for additional information related to these interventions.	Exposure to excessive moisture contributes to skin damage and pressure injury development due to decreased tissue tolerance and increases susceptibility to friction, pressure, and shear (Baranoski & Ayello, 2020; Gray & Guiliano, 2018; Voegili, 2019; WOCN, 2016).
15. Provide appropriate interventions to support the patient's nutritional status and ensure adequate nutritional and fluid intake (Kalowes, 2018). Interventions may include strategies to enhance oral intake, high-calorie/high-protein nutritional supplements, fortified foods, and/or enteral or parenteral nutritional support (Baranoski & Ayello, 2020; Munoz et al., 2020). Collaborate with the registered dietician and dietary staff to develop an individualized nutrition intervention plan (Kawoles, 2018; EPUAP, NPIAP, & Pan Pacific Pressure Injury Alliance, 2019a).	Adequate calories, protein, fluids, vitamins, and minerals are required for health and tissue maintenance (Kalowes, 2018; McNichol et al., 2022). Nutritional management is an important aspect of a comprehensive care plan for pressure injury prevention (Bergstrom et al., 2018; EPUAP, NPIAP, & PPPIA, 2019; Lovegrove et al., 2020; Munoz et al., 2020; WOCN, 2016).
16. Implement interventions to prevent pressure injury related to the use of medical devices, based on the individual patient's situation.	Interventions are necessary to prevent pressure injury related to the use of medical devices (Camacho-Del Rio, 2018; Joint Commission, 2018; EPUAP, NPIAP, & PPPIA, 2019a; WOCN, 2016).
a. Ensure correct for patient size and application of devices in use.	Correct size and accurate application minimize pressure and shear.
b. Use prophylactic dressings under the device, as appropriate to the individual patient and clinical use (EPUAP, NPIAP, & PPPIA, 2019a).	Appropriate use of prophylactic dressing manages moisture and provides cushioning to reduce pressure (EPUAP, NPIAP, & PPPIA, 2019a).
c. Inspect the skin under the devices and observe for edema under the devices more than twice daily or more often, as indicated.	Presence of edema increases risk for alterations in skin integrity (EPUAP, NPIAP, & PPPIA, 2019a).
d. Remove device as soon as medically feasible. Routinely reposition or rotate any medical device daily when possible.	Removal prevents pressure injury. Repositioning or rotating redistributes pressure and decreases shear (EPUAP, NPIAP, & PPPIA, 2019a).
e. Keep the skin clean and dry under medical devices.	Moisture underneath medical device increases risk of alterations in skin integrity (Camacho-Del Rio, 2018).
17. Provide education to the patient and caregiver(s) about the prevention plan and ways to minimize the risk of pressure injury.	These measures promote a collaborative relationship in which the patient is treated with respect. Explanation encourages patient understanding and engagement and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	reduces apprehension. Patient and caregiver education assist patients to implement behaviors to meet goals for care (EPUAP, NPIAP, & PPPIA, 2019a; McNichol et al., 2022; WOCN, 2016).
 18. Remove gloves and additional PPE, if used. Perform hand hygiene.	Removing gloves and PPE properly reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the transmission of microorganisms.
19. Evaluate the patient's response to interventions. Reassess and alter care plan as indicated by facility policies and procedures, as appropriate.	Evaluation allows for individualization of care plan and promotes optimal patient comfort.

DOCUMENTATION

GUIDELINES

Document risk and skin assessments, as well as other appropriate assessments, based on individual patient circumstances. Document interventions provided and patient responses. Record alternative treatments to consider, if appropriate. Document reassessment after interventions, at an appropriate interval, based on specific interventions used. Documentation related to pressure injury prevention is often completed on checklists or other tools on the patient's health record. Include any pertinent patient and family/caregiver education provided.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient develops a pressure injury:* Reassess the patient's condition. Perform assessment to differentiate pressure injuries from wounds and/or injuries due to other causes (WOCN, 2016). Consult with the patient's health care team regarding the injury and collaborate on a revised plan of care. Review and revise the current care plan to reflect the change in the patient's status and ensure implementation of appropriate nursing interventions. Implement appropriate wound care as prescribed and indicated in facility policy. Continue vigilant preventive interventions to avoid further pressure injury.

SPECIAL CONSIDERATIONS

GENERAL CONSIDERATIONS

- Preventive interventions related to pressure injury prevention should be based on nursing clinical judgment, the use of a reliable risk assessment tool, and assessment of individual patient extrinsic and intrinsic risk factors (EPUAP, NPIAP, & PPPIA, 2019a; WOCN, 2016). Interdisciplinary collaboration and communication are essential to pressure injury prevention in high-risk patient populations (Bergstrom et al., 2018).
- Extended use of prone positioning should be avoided unless required for management of the patient's medical condition; special consideration must be given to offloading of pressure points on the face, breast region, knees, toes, penis, clavicles, iliac crest and symphysis pubis, as well as the potential for uneven distribution of pressure and positioning of medical devices (EPUAP, NPIAP, & PPPIA, 2019a).
- Nurses must participate in continued pressure injury prevention and treatment education to ensure provision of evidence-based nursing care, achieve desired outcomes, and provide patients the best possible care (EPUAP, NPIAP, & PPPIA, 2019a).
- WOCN (2016) has developed a content-validated algorithm for support surface selection. This evidence- and consensus-based algorithm for support surface selection had a Content Validity Index (CVI) of 0.95 with an overall mean score of 3.72, indicating strong content validity and steps that are appropriate to the purpose of the algorithm (McNichol et al., 2015). Visit the WOCN website at https://www.wocn.org/learning-center/clinical-tools/ to access evidence for practice describing the Support Surface Algorithm, including the algorithm (McNichol et al., 2015); the interactive Support Surface Algorithm tool; and additional Support Surface Algorithm resources (WOCN, n.d.).

Infant and Child Considerations

- An age-appropriate risk assessment for pediatric, adolescent, and neonate populations considers risk factors of specific concern, including activity and mobility levels, skin texture and maturity, perfusion and oxygenation measures, presence of an external device, sensory perception, humidity, nutrition, friction and sheer, severity of illness, and duration of hospitalization (EPUAP, NPIAP, & PPPIA, 2019a; Ferreira et al., 2018).

Community-Based Care Considerations

- Pressure injury prevention in home settings can be challenging and may be compromised by access to resources and devices. Assessment of the patient and individual risk factors, as well as implementation of pressure injury prevention interventions in the home are critical in meeting patients' needs (Ellis, 2017; McGraw, 2018).
- Education of the patient, family, and caregivers is critical to ensure successful implementation of the pressure injury prevention care plan (Payne, 2016).

Skill 33-2

Cleaning a Wound and Applying a Dressing (General Guidelines)

DELEGATION CONSIDERATIONS

Wound care and procedures requiring the use of a sterile field and other sterile items are not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, these procedures may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Sterile gloves, as indicated
- Gloves
- Additional PPE, as indicated
- Primary and secondary dressings (if indicated) as prescribed
- Sterile dressing set or suture set (for the sterile scissors and forceps)
- Sterile cleaning solution as prescribed (commonly 0.9% normal saline solution, or a commercially prepared wound cleanser)
- Skin protectant/barrier wipes
- Sterile basin (may be optional)
- Sterile drape (may be optional)
- Plastic bag or other appropriate waste container for soiled dressings
- Waterproof pad and bath blanket
- Bath blanket or other linens for draping patient
- Additional dressings and supplies needed or required based on the wound dressing/care prescribed for the patient

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for prescribed wound care or the care plan related to wound care. Gather necessary supplies.	Reviewing the health record and care plan validates the correct patient and correct procedure. Preparation promotes efficient time management and an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.
5. Close the curtains around the bed and close the door to the room, if possible. Explain to the patient what	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

you are going to do and why you are going to do it.	
6. Assess the patient for the possible need for nonpharmacologic pain-reducing interventions or analgesic medication before wound care dressing change. Administer appropriate prescribed analgesic. Allow enough time for the analgesic to achieve its effectiveness.	Pain is a subjective experience influenced by past experience. Wound care and dressing changes may cause pain for some patients.
7. Place a waste receptacle or bag at a convenient location for use during the procedure.	Having a waste container handy means the soiled dressing may be discarded easily, without the spread of microorganisms.
8. Adjust the bed to a comfortable working height (VHA Center for Engineering & Occupational Safety and Health [CEOSH], 2016).	Having the bed at the proper height prevents back and muscle strain.
9. Assist the patient to a comfortable position that provides easy access to the wound area. Use the bath blanket to cover any exposed area other than the wound. Place a waterproof pad under the wound site.	Patient positioning and the use of a bath blanket provide for comfort and warmth. Waterproof pad protects underlying surfaces.
10. Check the position of drains, tubes, or other adjuncts before removing the dressing. Put on gloves and loosen the tape or adhesive edge on the old dressings by removing in the direction of hair growth and the use of a push–pull method (Fumarola et al., 2020) (Figure 1). Push–pull method: lift a corner of the dressing away from the skin, and then gently push the skin down and away from the dressing/adhesive (Fumarola et al., 2020). Continue moving fingers of the opposite hand to support the skin as the product is removed (Fumarola et al., 2020). Once all adhesive is loosened from the skin, carefully lift dressing from the surrounding skin to prevent medical adhesive–related skin injury (MARSI). Remove the sides/edges first, then the center. If the patient is at increased risk for MARSI, requires repeated application or removal of adhesive devices, or there is resistance, use an adhesive remover (Barton, 2020; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).	Checking ensures that a drain is not removed accidentally if one is present. Gloves protect the nurse from contaminated dressings and prevent the spread of microorganisms. Removal of the tape in the direction of hair growth minimizes trauma to the skin (Fumarola et al., 2020). Pushing the skin down and away from the adhesive reduces the risk for medical adhesive–related skin injury (MARSI) (Fumarola et al., 2020). The use of adhesive remover allows for the easy, rapid, and painless removal without the associated problems of skin stripping and helps reduce patient discomfort (Barton, 2020; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).
11. Carefully remove the soiled dressings. If any part of the dressing sticks to the underlying skin, use small amounts of sterile saline to help loosen and remove it.	Cautious removal of the dressing is more comfortable for the patient and ensures that any drain present is not removed. Sterile saline moistens the dressing for easier removal and minimizes damage and pain.
12. After removing the dressing, note the presence, amount, type, color, and odor of any drainage on the dressings (Figure 2). Place soiled dressings in the appropriate waste receptacle. Remove your gloves and perform hand hygiene.	The presence of drainage should be documented. Proper disposal of soiled dressings and used gloves prevents the spread of microorganisms. Hand hygiene prevents the transmission of microorganisms.

FIGURE 1. Loosening dressing tape or adhesive edge.

FIGURE 2. Noting characteristics of drainage on dressing that has been removed.

13.	Inspect the wound site for size, appearance, and drainage. Assess if any pain is present. Check the status of sutures, adhesive closure strips, staples, and drains or tubes, if present. Note any problems to include in your documentation.	Wound healing or the presence of irritation or infection should be documented.
14.	**Using sterile technique, prepare a sterile work area and open the needed supplies.**	Supplies are within easy reach and sterility is maintained.
15.	Open the sterile cleaning solution. Moisten gauze for cleaning the peri-wound skin. Depending on the amount of cleaning needed, the solution might be poured directly over gauze sponges over a container for small cleaning jobs, or into a basin for more complex or larger cleaning.	Sterility of dressings and solution is maintained.
16.	Put on sterile gloves. Alternatively, clean gloves (clean technique) may be used when cleaning a chronic wound or pressure injury.	The use of sterile gloves maintains surgical asepsis and sterile technique and reduces the risk for spreading microorganisms. Aseptic technique should be used to change dressings for surgical wounds and in the acute clinical setting, to reduce the risk of transfer of pathogens, likely to be present in an acute care setting, to the wound (Brown, 2018). Clean technique is appropriate for cleaning chronic wounds, wounds in the home, or pressure injuries (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a).
17.	Clean the wound. Pour the cleaning solution over the wound from top to bottom. Alternatively, spray the wound from top to bottom with a commercially prepared wound cleanser. Wound irrigation is often used to clean open wounds and may also be used for other types of wounds. Refer to Skill 33-3.	Cleaning from top to bottom and center to outside ensures that cleaning occurs from the least to most contaminated area and a previously cleaned area is not contaminated again. Using a single gauze for each wipe ensures that the previously cleaned area is not contaminated again.
18.	Clean the skin surrounding the wound. Clean from top to bottom and/or from the center to the outside, beginning at the wound edges (Figure 3). Use new gauze for each wipe, placing the used gauze in the waste receptacle.	Cleaning from top to bottom and center to outside ensures that cleaning occurs from the least to most contaminated area and a previously cleaned area is not contaminated again. Using a single gauze for each wipe ensures that the previously cleaned area is not contaminated again.
19.	Once the wound and surrounding skin are cleaned, dry the surrounding skin area using a gauze sponge in the same manner.	Excess moisture on healthy skin increases risk for moisture-associated skin damage and interferes with proper adhesion of securement of dressings.
20.	If a drain is in use at the wound location, clean around the drain. Refer to Skills 33-4 and 33-5.	Cleaning the insertion site helps prevent infection.
21.	Remove gloves and place in the waste	Proper disposal of used gloves and hand hygiene prevent

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

receptacle. Perform hand hygiene.

the spread of microorganisms.

22. Put on sterile gloves. Alternatively, clean gloves (clean technique) may be used when cleaning a chronic wound or pressure injury. Apply a skin protectant or barrier to the healthy skin around the wound where the dressing adhesive or tape will be placed and where wound drainage may come in contact with the skin (Figure 4).

The use of sterile gloves maintains surgical asepsis and sterile technique and reduces the risk for spreading microorganisms. Clean technique is appropriate for cleaning chronic wounds, wounds in the home, or pressure injuries (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a). Skin barrier/protectant prevents skin irritation and excoriation from tape, adhesives, and wound drainage (Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).

FIGURE 3. Cleaning the wound.

FIGURE 4. Applying skin protectant to skin surrounding wound.

23. Apply any topical medications, foams, gels, and/or dressing product to the wound as prescribed; ensure products stay confined to the wound and do not impact on intact surrounding tissue/skin (Figure 5).

The growth of microorganisms may be inhibited and the healing process improved with the use of prescribed medications, foams, gels, and/or other wound care product.

24. Gently place the prescribed cover dressing at the wound center and extend it at least 1 inch beyond the wound in all directions. Alternatively, follow the manufacturer's directions for application (Figure 6).

Extending the dressing at least 1 inch past the wound edges ensures the dressing covers and protects the wound.

FIGURE 5. Applying prescribed wound care product.

FIGURE 6. Applying cover dressing to site.

25. As necessary, apply a secondary dressing, based on products in use, prescribed interventions, and facility policy. Note: May not be necessary or appropriate, based on the cover dressing used in Step 23. Some dressings act as both primary and secondary dressings (Baranoski & Ayello, 2020).

Secondary dressings cover the primary dressing or secure the dressing (Baranoski & Ayello, 2020).

26. Apply additional materials, such as roller

Additional securing products keep the dressing in place.

 gauze, to secure the dressings as needed. Alternatively, many commercial wound products are self-adhesive and do not require additional tape. Remove gloves and perform hand hygiene.	Proper disposal of gloves and hand hygiene prevent the spread of microorganisms.
27. Label the dressing with date and time. Remove all remaining equipment; place the patient in a comfortable position, with side rails up as indicated and bed in the lowest position.	Recording date and time provides communication and demonstrates adherence to care plan. Proper patient and bed positioning promotes safety and comfort.
 28. Remove PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
29. Check all wound dressings at least every shift. More frequent checks may be needed if the wound is more complex.	Checking dressings ensures the assessment of changes in patient condition and timely intervention to prevent complications.

DOCUMENTATION

GUIDELINES

Document the location of the wound and that the dressing was removed. Record your assessment of the wound: size; approximation of wound edges; presence of sutures, staples, or adhesive closure strips if wound edges are approximated; record size and wound assessment if wound edges are not approximated; and the condition of the surrounding skin. Note if redness, edema, or drainage is observed and document characteristics if present. Document cleansing of wound and application of topical medications, foams, gels, and/or gauze to the wound as prescribed. Record the type of dressing that was reapplied. Note pertinent patient and family/caregiver education and any patient reaction to the procedure, including patient's pain level and effectiveness of nonpharmacologic interventions or analgesia if administered.

Sample Documentation

Practice documenting wound care in *Lippincott DocuCare.*

9/8/25 0600 Dressing removed from left lateral calf incision. Scant purulent secretions noted on dressing. Incision edges approximately 1 mm apart, red, with ecchymosis and edema present. Small amount of purulent drainage from wound noted. Area cleansed with normal saline; antibiotic ointment applied as prescribed. Surrounding tissue red and ecchymotic. Redressed with nonadhering dressing and wrapped with stretch gauze. Patient reports adequate pain control after preprocedure analgesic; states pain is dull ache, 1/10 on pain scale.

—N. Joiner, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *The previous wound assessment states that the incision was clean and dry, and the wound edges were approximated, with the staples and surgical drain intact. The surrounding tissue was without inflammation, edema, or erythema. After the dressing is removed, the nurse notes the incision edges are not approximated at the distal end, multiple staples are evident in the old dressing, the surrounding skin tissue is red and swollen, and purulent drainage is on the dressing and leaking from the wound:* Assess the patient for any other signs and symptoms, such as pain, malaise, fever, and paresthesias. Place a dry sterile dressing over the wound site. Report the findings to the health care team and document the event in the patient's record. Be prepared to obtain a wound culture and implement any changes in wound care as prescribed.
- *When removing a patient's dressing, the assessment reveals deterioration or significant improvement in the wound:* Notify the health care team or wound care specialist, as a different treatment modality and/or dressing product may be necessary.

SPECIAL CONSIDERATIONS

General Considerations

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Instruct the patient, if appropriate, and other members of the health care team to observe for excessive drainage that may overwhelm the dressing. They should also report when dressings become soiled or loosened from the skin.
- There are many dressing types and manufacturers—the nurse needs to collaborate with the health care team to ensure the correct dressing type is chosen, ongoing assessment occurs, and updates to the treatment plan (dressing choice) are made as the wound evolves. The choice of wound dressing will change during the healing period, based on a minimum of once-a-week wound assessment (more often with notable changes) (Baranoski & Ayello, 2020). The type of wound and status/characteristics of the wound influence the choice of the wound dressing, and several different types of products may be needed as the wound progresses through the stages of healing (Baranoski & Ayello, 2020, p. 191).
- Products designed to assist with dressing removal can reduce pain, avoid damaging the periwound skin and resulting skin stripping and MARSI and result in time savings (Fumarola et al., 2020; Kelly-O'Flynn et al., 2020; Reevell et al., 2016).
- When using adherent dressings, such as a hydrocolloid dressing, cut the dressing to size, allowing at least a 1-inch margin of healthy skin around the wound to be covered with the dressing (Baranoski & Ayello, 2020). Apply the dressing to the wound without stretching the dressing.
- Optimum and timely wound healing are supported by adequate nutrition and hydration (Dudek, 2018; Stuart, 2020). Collaborate with the registered dietician and dietary staff to develop an individualized nutrition intervention plan for the patient.

Infant and Child Considerations

- The skin of neonates is more fragile as a result of incomplete epidermal-to-dermal cohesion; use skin barrier products and adhesive removers, paper tape, or nonadherent dressings to prevent tearing of the skin (Baranoski et al., 2016; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).

Older Adult Considerations

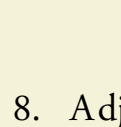
- The skin of older adults is less elastic and more fragile as a result of age-related changes; use skin barrier products and adhesive removers, paper tape, nonadherent dressings, or roller gauze (on extremities) to prevent tearing of the skin (Baranoski et al., 2016; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).

Community-Based Care Considerations

- Patients may shower to clean the wound before dressing changes in the community; patients should avoid using perfumed soaps, body wash, or antiseptics or soaps and instead use pH neutral shower and bath skin cleansers/emollients (Brown, 2018; Milne, 2019).
- Saline solution can be prepared at home by combining 1 teaspoon of noniodized salt with 1 quart of distilled water and stirring until the salt is completely dissolved (Baranoski & Ayello, 2020). This solution can be kept in a tightly covered glass or plastic container for up to 1 week at room temperature (Baranoski & Ayello, 2020).

Skill 33-3 Performing Irrigation of a Wound

DELEGATION CONSIDERATIONS



Irrigation of a wound and procedures requiring the use of a sterile field and other sterile items are not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, these procedures may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- An 18- to 19-gauge needle/angiocath and 30- to 35-mL syringe or a commercial cleanser packaged in a pressurized container (Baranoski & Ayello, 2020, p. 152; McLain & Moore, 2021; WOCN, 2016)
- Sterile irrigation solution as prescribed, warmed to body temperature, commonly 0.9% normal saline solution or other solution as prescribed
- Alternatively, irrigation solution may be packaged in individual, single-use syringe
- Plastic bag or other waste container to dispose of soiled dressings
- Sterile gloves
- Sterile drape (may be optional)

- Clean, disposable gloves
- Moisture-proof gown; mask, and eye protection or face shield
- Waterproof pad and bath blanket
- Bath blanket or other linens for draping patient
- Additional PPE, as indicated
- Additional dressings and supplies needed or required based on the wound dressing/care prescribed for the patient

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for prescribed wound care or the plan of care related to wound care. Gather necessary supplies.	Reviewing the health record and care plan validates the correct patient and correct procedure. Preparation promotes efficient time management and an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.
5. Close the curtains around the bed and close the door to the room if possible. Explain what you are going to do and why you are going to do it to the patient.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement.
6. Assess the patient for possible need for nonpharmacologic pain-reducing interventions or analgesic medication before wound care and/or dressing change. Administer appropriate prescribed analgesic. Allow enough time for the analgesic to achieve its effectiveness before beginning the procedure.	Pain is a subjective experience influenced by past experience. Wound care and dressing changes may cause pain for some patients.
7. Place a waste receptacle or bag at a convenient location for use during the procedure.	Having a waste container handy means the soiled dressing may be discarded easily, without the spread of microorganisms.
8. Adjust the bed to a comfortable working height (VHACEOSH, 2016).	Having the bed at the proper height prevents back and muscle strain.
9. Assist the patient to a comfortable position that provides easy access to the wound area. Position the patient so the irrigation solution will flow from the clean end of the wound toward the dirtier end or top to bottom. Use the bath blanket to cover any exposed area other than the wound. Place a waterproof pad under the wound site.	Patient positioning and the use of a bath blanket provide for comfort and warmth. Gravity directs the flow of liquid from the least contaminated to the most contaminated area. Waterproof pad protects underlying surfaces.
10. Put on a gown, mask, and eye protection or face shield.	Using PPE, such as gowns, masks, and eye protection, is part of *Standard Precautions*. A gown protects clothes from contamination should splashing occur. Appropriate personal protective equipment, including a mask and eye protection or face shield is essential when irrigating a wound with any degree of pressure (WOCN, 2016).
11. Check the position of drains, tubes, or other adjuncts	Checking ensures that a drain is not removed accidentally

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

before removing the dressing. Put on clean, disposable gloves and loosen the tape on the old dressings by removing in the direction of hair growth and the use of a push–pull method (see Figure 1, Skill 33-2) (Fumarola et al., 2020). Push–pull method: lift a corner of the dressing away from the skin, then gently push the skin away from the dressing/adhesive (Fumarola et al., 2020). Continue moving fingers of the opposite hand to support the skin as the product is removed (Fumarola et al., 2020). Once all adhesive is loosened from the skin, carefully lift dressing from the surrounding skin to prevent medical adhesive–related skin injury (MARSI). Remove the sides/edges first, then the center. If the patient is at increased risk for MARSI, requires repeated application or removal of adhesive devices, or there is resistance, use an adhesive remover (Barton, 2020; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).	if one is present. Gloves protect the nurse from contaminated dressings and prevent the spread of microorganisms. Removal of the tape in the direction of hair growth minimizes trauma to the skin (Fumarola et al., 2020). The use of adhesive remover allows for the easy, rapid, and painless removal without the associated problems of skin stripping and helps reduce patient discomfort (Barton, 2020; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).
12. Carefully remove the soiled dressings. If any part of the dressing sticks to the underlying skin, use small amounts of sterile saline to help loosen and remove it.	Cautious removal of the dressing is more comfortable for the patient and ensures that any drain present is not removed. Sterile saline moistens the dressing for easier removal and minimizes damage and pain.
13. After removing the dressing, note the presence, amount, type, color, and odor of any drainage on the dressings. Place soiled dressings in the appropriate waste receptacle.	The presence of drainage should be documented. Proper disposal of soiled dressings and used gloves prevents the spread of microorganisms.
14. Assess the wound for appearance, stage, presence of eschar, granulation tissue, epithelialization, undermining, tunneling, necrosis, sinus tract, and drainage. Assess the appearance of the surrounding tissue. Measure the wound.	This information provides evidence about the wound healing process and/or the presence of infection.
 15. Remove your gloves and put them in the receptacle. Perform hand hygiene.	Discarding gloves prevents the spread of microorganisms. Hand hygiene prevents the spread of microorganisms.
16. Set up a sterile field, if indicated, and wound cleaning and irrigation supplies. Pour warmed sterile irrigating solution into the sterile container (based on supplies in use). Moisten gauze for cleaning the periwound skin. Put on the sterile gloves. Alternatively, clean gloves (clean technique) may be used when cleaning a chronic wound or pressure injury.	Using warmed solution prevents chilling the patient and may minimize patient discomfort. Aseptic technique should be used to change dressings for surgical wounds and in the acute clinical setting, to reduce the risk of transfer of pathogens, likely to be present in an acute care setting, to the wound (Brown, 2018). Clean technique is appropriate for cleaning chronic wounds, wounds in the home, or pressure injuries (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a).
17. Position the sterile basin below the wound to collect the irrigation fluid.	Patient and bed linens are protected from contaminated fluid.
18. Fill the irrigation syringe with solution (Figure 1). Alternatively, irrigation solution may be packaged in individual, single-use syringe; remove cap on syringe. Using your nondominant hand, gently apply pressure to the basin against the skin below the wound to form a seal with the skin (Figure 2).	The solution will collect in the basin and prevent the irrigant from running down the skin. Patient and bed linens are protected from contaminated fluid.

FIGURE 1. Drawing up sterile solution from sterile container into irrigation syringe.

FIGURE 2. Applying pressure to basin to form seal.

19.	Using either a pulsatile or continuous flow pattern, direct a stream of solution into the wound from top to bottom (Figure 3). Flush all wound areas.	The wound irrigating fluid stream can be delivered in either a pulsatile or continuous flow pattern (Baranoski & Ayello, 2020). Directing flow from top to bottom ensures that a previously cleaned area is not contaminated again.

FIGURE 3. Irrigating wound with a stream of solution. Solution drains into collection container.

20.	Watch for the solution to flow smoothly and evenly. When the solution from the wound flows out clear, discontinue irrigation.	Irrigation removes exudate and debris.
21.	Once the wound is cleaned, clean the skin surrounding the wound and then dry the skin surrounding the wound (Figure 4). (Refer to Steps 18 and 19, Skill 33-2.)	Excess moisture on healthy skin increases risk for moisture-associated skin damage and interferes with proper adhesion of securement of dressings.
22.	If a drain is in use at the wound location, clean around the drain. Refer to Skills 33-4 and 33-5.	Cleaning the insertion site helps prevent infection.
23.	Remove gloves and perform hand hygiene.	Proper disposal of used gloves and hand hygiene prevent the spread of microorganisms.
24.	Redress the wound, applying any topical medications, foams, gels, and/or gauze to the wound (Figure 5) and based on type of dressing prescribed or in use. (Refer to Skill 33-2 for general guidelines.)	Provides appropriate wound care to support plan of care.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 4. Drying around wound, not in wound, with gauze pad.

FIGURE 5. Applying wound contact material.

25. Remove PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

26. Check all wound dressings at least every shift. More frequent checks may be needed if the wound is more complex.

Checking dressings ensures the assessment of changes in patient condition and timely intervention to prevent complications.

DOCUMENTATION

Guidelines

Document the location of the wound and that the dressing was removed. Record your assessment of the wound, including evidence of granulation tissue, presence of necrotic tissue, stage (if pressure injury), and characteristics of drainage. Include the appearance of the surrounding skin. Document the irrigation of the wound and solution used. Record the type of dressing that was applied. Note pertinent patient and family/caregiver education and any patient reaction to this procedure, including patient's pain level and effectiveness of nonpharmacologic interventions or analgesia if administered.

Sample Documentation

3/5/25 1700 Dressing removed from left outer heel area. Minimal serosanguineous drainage noted on dressings. Wound 4 cm × 5 cm × 2 cm, pink, with granulation tissue evident. Surrounding skin tone consistent with patient's skin, no edema or redness noted. Irrigated with normal saline and hydrogel dressing applied.

—J. Lark, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient experiences pain when the wound irrigation is begun:* Stop the procedure and administer an analgesic, as prescribed. Obtain new sterile supplies and begin the procedure after an appropriate amount of time has elapsed to allow the analgesic to begin working. Note the patient's pain on the plan of care so that pain medication can be given before future wound treatments.
- *During the wound irrigation, the nurse notes bleeding from the wound. This has not been documented as happening with previous irrigations:* Stop the procedure. Assess the patient for other symptoms. Obtain vital signs. Report the findings to the health care team and document the event in the patient's record.

SPECIAL CONSIDERATIONS

- Optimum and timely wound healing are supported by adequate nutrition and hydration (Dudek, 2018; EPUAP, NPIAP, & PPPIA, 2019a; Stuart, 2020). Collaborate with the registered dietician and dietary staff to develop an individualized nutrition intervention plan for the patient.
- A whirlpool bath may be prescribed as an alternative to irrigation for some chronic wounds (Baranoski & Ayello, 2020). The wound should not come in close contact with the water jets in the whirlpool to avoid tissue injury.

Skill 33-4

Caring for a Jackson-Pratt Drain

DELEGATION CONSIDERATIONS

Care for a JP drain insertion site is not delegated to assistive personnel (AP). Depending on the organization's policies and procedures, the drain may be emptied and reconstituted by AP. Depending on the state's nurse practice act and the organization's policies and procedures, these procedures may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Graduated container for measuring drainage
- Clean, disposable gloves
- Additional PPE, as indicated
- Cleansing solution, usually sterile normal saline
- Sterile gauze pads
- Skin protectant/barrier wipes
- Sterile drain sponges
- Sterile gloves
- Sterile cotton-tipped applicators, if appropriate
- Sterile container to hold cleaning solution
- Plastic bag or other appropriate waste container for soiled dressings
- Waterproof pad and bath blanket
- Additional dressings and supplies needed or as required for prescribed wound care

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for prescribed wound care or the plan of care related to wound/drain care. Gather necessary supplies.	Reviewing the health record and care plan validates the correct patient and correct procedure. Preparation promotes efficient time management and organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.
5. Close the curtains around the bed and close the door to the room, if possible. Explain what you are going to do and why you are going to do it to the patient.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement.
6. Assess the patient for possible need for nonpharmacologic pain-reducing interventions or analgesic medication before wound care dressing change. Administer appropriate prescribed analgesic. Allow enough time for the analgesic to achieve its effectiveness before beginning the procedure.	Pain is a subjective experience influenced by past experience. Wound care and dressing changes may cause pain for some patients.
7. Place a waste receptacle at a convenient location for	Having a waste container handy means that the soiled

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

use during the procedure.	dressing may be discarded easily, without the spread of microorganisms.
8. Adjust the bed to a comfortable working height (VHACEOSH, 2016).	Having the bed at the proper height prevents back and muscle strain.
9. Assist the patient to a comfortable position that provides easy access to the drain and/or wound area. Use a bath blanket to cover any exposed area other than the drain. Place a waterproof pad under the drain site.	Patient positioning and the use of a bath blanket provide for comfort and warmth. Waterproof pad protects underlying surfaces.
Emptying Drainage	
10. Put on gloves; put on mask or face shield, as indicated.	Gloves prevent the spread of microorganisms; mask reduces the risk of transmission should splashing occur.
11. Using sterile technique, open a gauze pad, making a sterile field with the outer wrapper.	Using sterile technique deters the spread of microorganisms.
12. Place the graduated collection container under the drain outlet. Without contaminating the outlet valve, pull off the cap. The chamber will expand completely as it draws in air. **Empty the chamber's contents completely into the container (Figure 1). Use the gauze pad to wipe the outlet. With one hand, fully compress the chamber along the long axis, side to side** (Mamuyac et al., 2019), **and replace the cap with your other hand (Figure 2).**	Emptying the drainage allows for accurate measurement. Cleaning the outlet reduces the risk of contamination and helps prevent the spread of microorganisms. Compressing the chamber along the long axis, side to side, reestablishes the suction. And generates higher negative pressure compared to the bottom-up methods (Mamuyac et al., 2019).

FIGURE 1. Emptying contents of Jackson-Pratt drain into collection container.

FIGURE 2. Compressing Jackson-Pratt drain and replacing cap.

13. Check the patency of the equipment. Bulb should remain compressed (Figure 3). **Check that the tubing is free from twists and kinks.**	Compressed chamber establishes suction. Patent, untwisted, or unkinked tubing promotes appropriate wound drainage.

FIGURE 3. Compressed drain bulb.

14. Carefully measure and record the character, color, and amount of the drainage. Discard the drainage according to facility policy.	Documentation promotes continuity of care and communication. Appropriate disposal of biohazard material reduces the risk for microorganism transmission.
15. Remove gloves. Perform hand hygiene.	Removal of gloves and hand hygiene prevents the transmission of microorganisms.

Cleaning the Drain Site

16. Put on gloves. Check the position of the drain or drains before removing the dressing. Loosen the tape on the old dressings by removing in the direction of hair growth and the use of a push–pull method (Fumarola et al., 2020). Push–pull method: lift a corner of the dressing away from the skin, and then gently push the skin down and away from the dressing/adhesive (Fumarola et al., 2020). Continue moving fingers of the opposite hand to support the skin as the product is removed (Fumarola et al., 2020). Once all adhesive is loosened from the skin, carefully lift dressing from the surrounding skin to prevent medical adhesive–related skin injury (MARSI). Remove the sides/edges first, then the center. If the patient is at increased risk for MARSI, requires repeated application or removal of adhesive devices, or there is resistance, use an adhesive remover (Barton, 2020; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).	Gloves protect the nurse from contaminated dressings and prevent the spread of microorganisms. Dressing protects the site. Checking ensures that a drain is not removed accidentally. Removal of the tape in the direction of hair growth minimizes trauma to the skin (Fumarola et al., 2020). Pushing the skin down and away from the adhesive reduces the risk for medical adhesive–related skin injury (MARSI) (Fumarola et al., 2020). The use of adhesive remover allows for the easy, rapid, and painless removal without the associated problems of skin stripping and helps reduce patient discomfort (Barton, 2020; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).
17. Carefully remove the soiled dressings. If any part of the dressing sticks to the underlying skin, use small amounts of sterile saline to help loosen and remove it.	Cautious removal of the dressing is more comfortable for the patient and ensures that any drain present is not removed. Sterile saline moistens the dressing for easier removal and minimizes damage and pain.
18. Note the presence, amount, type, color, and odor of any drainage on the dressings. Place soiled dressings in the appropriate waste receptacle. Remove your gloves and perform hand hygiene.	The presence of drainage should be documented. Proper disposal of soiled dressings and used gloves prevents the spread of microorganisms. Hand hygiene prevents the transmission of microorganisms.
19. Inspect the drain site for appearance and drainage. Assess if any pain is present. Check the status of	The wound healing process and/or the presence of irritation or infection must be documented.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

sutures, adhesive closure strips, and staples, if present. Note any problems to include in your documentation.	
 20. Remove gloves and perform hand hygiene.	Removal of gloves and performance of hand hygiene prevent transmission of microorganisms.
21. **Using sterile technique, prepare a sterile work area and open the needed supplies.** Refer to facility policy and prescribed interventions regarding use of a sterile approach to site care.	Supplies are within easy reach and sterility is maintained. A sterile dressing is usually maintained for 24 to 48 hours; the use of a dressing after this time depends on the site assessment and amount of drainage (Orth, 2018). The site may be treated as an additional surgical wound, but often these sites are left open to air 24 hours after surgery. Refer to facility policy and prescribed interventions regarding need for sterile approach to site care and use of dressing.
22. Open the sterile cleaning solution. Pour it into the basin. Add the gauze sponges.	Sterility of dressings and solution is maintained.
23. Put on sterile gloves. Alternatively, clean gloves (clean technique) may be used based on facility policy and care setting.	The use of sterile gloves maintains surgical asepsis and sterile technique and reduces the risk of microorganism transmission. Clean technique is appropriate for cleaning chronic wounds, wounds in the home, or pressure injuries (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a).
24. Cleanse the drain site with the cleaning solution. Use the forceps and the moistened gauze or cotton-tipped applicators. **Start at the drain insertion site, moving in a circular motion toward the periphery. Use each gauze sponge or applicator only once.** Discard and use new gauze/applicator if additional cleansing is needed.	Cleaning is done from the least to most contaminated area so that a previously cleaned area is not contaminated again.
25. Dry with new sterile gauze in the same manner. Apply skin protectant/barrier to the skin around the drain; extend out to include the area of skin that will be taped.	Drying prevents skin irritation. Skin barrier/protectant prevents skin irritation and excoriation from tape, adhesives, and wound drainage (Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).
26. Place a pre-split drain sponge under the drain. Apply gauze pads or other cover dressing, such as a transparent dressing, as indicated by facility policy, over the drain. Secure the dressings with tape, as needed. Remove and discard gloves. Perform hand hygiene.	The gauze absorbs drainage and prevents the drainage from accumulating on the patient's skin. Transparent dressing, tape or other securing products keep the dressing in place. Proper disposal of gloves prevents the spread of microorganisms. Hand hygiene prevents the transmission of microorganisms.
27. Secure the drain tubing to the patient's skin using a tape or a commercial securement/stabilization device, allowing slack in the tubing to avoid excessive tension. **Be careful not to kink the tubing and ensure the collection bag remains below the drain site.** Label the dressing with date and time.	Securing the tubing prevents accidental dislodgement or movement and avoids excessive tension on tube. Kinked tubing could block drainage. Maintaining the drain collection bag remains below the drain site facilitates proper drainage. Recording date and time provides communication and demonstrates adherence to plan of care.
 28. Alternatively, if the drain site is open to air, observe the sutures that secure the drain to the skin. Look for signs of pulling, tearing, swelling, or infection of the surrounding skin. Gently clean the sutures with the gauze pad moistened with normal saline. Dry with a new gauze pad. Apply skin protectant/barrier to the	Early detection of problems leads to prompt intervention and prevents complications. Gentle cleaning and drying prevent the growth of microorganisms. Skin barrier/protectant prevents skin irritation and excoriation from tape, adhesives, and wound drainage (Fumarola et al., 2020; Kelly-O'Flynn et al., 2020). Proper removal of gloves prevents the spread of

surrounding skin. Remove and discard gloves. Perform hand hygiene.	microorganisms. Hand hygiene prevents the transmission of microorganisms.
29. Remove all remaining equipment; place the patient in a comfortable position, with side rails up as indicated and bed in the lowest position.	Proper patient and bed positioning promotes safety and comfort.
 30. Remove additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
31. Check drain status at least every 4 hours. Empty and reengage suction (compress device) when device is approximately 25% to 50% full (Mamuyac et al., 2019). Check all wound dressings at least every shift. More frequent checks may be needed if the wound is more complex, or dressings become saturated quickly.	Checking drain ensures proper functioning and early detection of problems. Emptying and compression ensure appropriate suction. Adequate suction pressure declines as bulb volume increases; bulb emptying should occur when the bulb is approximately 25% to 50% full for optimal accuracy and maintenance of adequate suction (Mamuyac et al., 2019; Yue et al., 2015). Checking dressings ensures the assessment of changes in patient condition and timely intervention to prevent complications.

DOCUMENTATION

Guidelines

Document the location of the drain, the assessment of the drain site, and patency of the drain. Note if sutures are intact. Document the presence and characteristics of drainage on the old dressing upon removal. Include the appearance of the surrounding skin. Document cleansing the drain site. Record any skin care and the dressing applied. Note that the drain was emptied and recompressed. Note pertinent patient and family/caregiver education and any patient reaction to this procedure, including patient's pain level and effectiveness of nonpharmacologic interventions or analgesia, if administered. Document the amount and characteristics of drainage obtained on the appropriate intake and output record.

Sample Documentation

2/7/25 2400 Right chest incision and drain open to air. Wound edges approximated, slight ecchymosis, no edema, redness, or drainage. Steri-Strips intact. JP drain patent and secured with suture. Exit site without edema, drainage, or redness; drain site cleaned with normal saline, and skin barrier applied. Drain emptied and recompressed. 40-mL sanguineous drainage recorded.

—C. White, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient has a JP drain in the right lower quadrant following abdominal surgery. The record indicates it has been draining serosanguineous fluid, 40 to 50 mL every shift. While performing your initial assessment, you note that the dressing around the drain site is saturated with serosanguineous secretions and there is minimal drainage in the collection chamber:* Inspect the tubing for kinks or obstruction. Assess the patient for changes in condition. Remove the dressing and assess the site. Often, if the tubing becomes blocked with a blood clot or drainage particles, the wound drainage will leak around the exit site of the drain. Cleanse the area and redress the site. Notify the health care team of the findings and document the event in the patient's record.
- *Patient calls you to the room and says, "I found this in the bed when I went to get up." He has his JP drain in his hand. It is completely removed from the patient:* Assess the patient for any new and abnormal signs or symptoms and assess the surgical site and drain site. Apply a sterile dressing the drain site. Notify the health care team of the findings and document the event in the patient's record.

SPECIAL CONSIDERATIONS

- A sterile dressing is usually maintained for 24 to 48 hours; the use of a dressing after this time depends on the site assessment and amount of drainage (Orth, 2018). The site may be treated as an additional surgical wound, but often

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

these sites are left open to air 24 hours after surgery. Refer to facility policy and prescribed interventions regarding need for sterile approach to site care and use of dressing.

- Often patients have more than one JP drain. Number or letter the drains for easy identification. Record the drainage from each drain separately, identified by the number or letter, on the intake and output record.
- When the patient with a drain is ready to ambulate, empty and compress the drain before activity. Secure the drain to the patient's gown below the wound, making sure there is no tension on the drainage tubing. This removes excess drainage, maintains maximum suction, and avoids strain on the drain's suture line.
- Appropriate nutritional support is critical in achieving successful wound healing and may be overlooked (Quain & Khardori, 2015). Collaborate with the registered dietician and dietary staff to develop an individualized nutrition intervention plan for the patient (Baranoski & Ayello, 2020).

Community-Based Care Considerations

- Drain site care in the community setting is a clean, not sterile, procedure. Patients will use soap and water to clean the skin around the drain site (Memorial Sloan Kettering Cancer Center, 2019).

Skill 33-5 Caring for a Hemovac Drain

DELEGATION CONSIDERATIONS

Care for a Hemovac drain insertion site is not delegated to assistive personnel (AP). Depending on the organization's policies and procedures, the drain may be emptied and reconstituted by AP. Depending on the state's nurse practice act and the organization's policies and procedures, these procedures may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Graduated container for measuring drainage
- Clean, disposable gloves
- Additional PPE, as indicated
- Cleansing solution, usually sterile normal saline
- Sterile gauze pads
- Skin protectant/barrier wipes
- Sterile gloves
- Sterile cotton-tipped applicators, if appropriate
- Sterile container to hold cleaning solution
- Plastic bag or other appropriate waste container for soiled dressings
- Waterproof pad and bath blanket
- Additional dressings and supplies needed or as required for prescribed wound care

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for prescribed wound care or the plan of care related to wound/drain care. Gather necessary supplies.	Reviewing the health record and care plan validates the correct patient and correct procedure. Preparation promotes efficient time management and an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.

4. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.
5. Close the curtains around the bed and close the door to the room, if possible. Explain what you are going to do and why you are going to do it to the patient.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement.
6. Assess the patient for possible need for nonpharmacologic pain-reducing interventions or analgesic medication before wound care dressing change. Administer appropriate prescribed analgesic. Allow enough time for analgesic to achieve its effectiveness before beginning the procedure.	Pain is a subjective experience influenced by past experience. Wound care and dressing changes may cause pain for some patients.
7. Place a waste receptacle at a convenient location for use during the procedure.	Having a waste container handy means that the soiled dressing may be discarded easily, without the spread of microorganisms.
8. Adjust the bed to a comfortable working height (VHACEOSH, 2016).	Having the bed at the proper height prevents back and muscle strain.
9. Assist the patient to a comfortable position that provides easy access to the drain and/or wound area. Use a bath blanket to cover any exposed area other than the drain. Place a waterproof pad under the drain site.	Patient positioning and the use of a bath blanket provide for comfort and warmth. Waterproof pad protects underlying surfaces.

Emptying Drainage

10. Put on gloves; put on mask or face shield, as indicated.	Gloves prevent the spread of microorganisms; mask reduces the risk of transmission should splashing occur.
11. Using sterile technique, open a gauze pad, making a sterile field with the outer wrapper.	Using sterile technique deters the spread of microorganisms.
12. Place the graduated collection container under the drain outlet. **Without contaminating the outlet, pull off the cap.** The chamber will expand completely as it draws in air. **Empty the chamber's contents completely into the container (Figure 1). Use the gauze pad to wipe the outlet. Place the container or a clean, flat surface. Fully compress the chamber by pushing down on the top until it meets the bottom and is flat** (Wechter, 2020b). **Keep the device tightly compressed while you apply the cap (Figure 2).**	Emptying the drainage allows for accurate measurement. Cleaning the outlet reduces the risk of contamination and helps prevent the spread of microorganisms. Compressing the chamber reestablishes the suction.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 1. Emptying Hemovac drain into collection container.

FIGURE 2. Compressing Hemovac and securing cap.

13. The device should remain compressed. Check the patency of the equipment. **Make sure the tubing is free from twists and kinks.**	Compressed device establishes suction. Patent, untwisted, or unkinked tubing promotes appropriate drainage from the wound.
14. Carefully measure and record the character, color, and amount of the drainage. Discard the drainage according to facility policy. Remove gloves. Perform hand hygiene.	Documentation promotes continuity of care and communication. Appropriate disposal of biohazard material reduces the risk for microorganism transmission. Proper disposal of gloves deters transmission of microorganisms. Hand hygiene prevents the transmission of microorganisms.

Cleaning the Drain Site

15. Put on gloves. If the drain site has a dressing, remove the dressing, assess and clean the site, and replace the dressing as outlined in Skill 33-4, Steps 16–26.	Dressing protects the site. Cleaning and drying sutures deters the growth of microorganisms.
16. Secure the drain tubing to the patient's skin using a tape or a commercial securement/stabilization device, allowing slack in the tubing to avoid excessive tension. **Be careful not to kink the tubing and ensure the collection bag remains below the drain site.** Label the dressing with date and time.	Securing the tubing prevents accidental dislodgement or movement and avoids excessive tension on tube. Kinked tubing could block drainage. Maintaining the drain collection bag remains below the drain site facilitates proper drainage. Recording date and time provides communication and demonstrates adherence to plan of care.
17. Alternatively, if the drain site is open to air, observe the sutures that secure the drain to the skin. Look for signs of pulling, tearing, swelling, or infection of the surrounding skin. Gently clean the sutures with the gauze pad moistened with normal saline. Dry with a new gauze pad. Apply skin protectant/barrier to the surrounding skin.	Early detection of problems leads to prompt intervention and prevents complications. Gentle cleaning and drying prevent the growth of microorganisms. Skin barrier/protectant prevents skin irritation and excoriation from tape, adhesives, and wound drainage (Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).
18. Remove and discard gloves. Perform hand hygiene.	Proper removal of gloves prevents the spread of microorganisms. Hand hygiene prevents the transmission of microorganisms.
19. Remove all remaining equipment; place the patient in a comfortable position, with side rails up as indicated and bed in the lowest position.	Proper patient and bed positioning promotes safety and comfort.
20. Remove additional PPE, if used. Perform hand	Proper removal of PPE reduces the risk for infection

	hygiene.	transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
21.	Check drain status at least every 4 hours. Empty and reengage suction (compress device) every 2 to 4 hours (Bauldoff et al., 2020) and when it is half full of drainage or air. Check all wound dressings at least every shift. More frequent checks may be needed if the wound is more complex, or dressings become saturated quickly.	Checking the drain ensures proper functioning and early detection of problems. Emptying and compression ensure appropriate suction. Checking dressings ensures the assessment of changes in patient condition and timely intervention to prevent complications.

DOCUMENTATION

Guidelines

Document the location of the drain, the assessment of the drain site, and patency of the drain. Note if sutures are intact. Document the presence and characteristics of drainage on the old dressing upon removal. Include the appearance of the surrounding skin. Document cleansing of the drain site. Record any skin care and any dressing applied. Note that the drain was emptied and recompressed. Note pertinent patient and family/caregiver education and any patient reaction to this procedure, including patient's pain level and effectiveness of nonpharmacologic interventions or analgesia, if administered. Document the amount and characteristics of drainage obtained on the appropriate intake and output record.

Sample Documentation

1/18/25 1000 Hemovac drain in place at lateral aspect of left knee. Gauze dressing removed; no drainage noted on dressing. Suture intact; exit site slightly pink, without redness, edema, or drainage. Surrounding skin without edema, ecchymosis, or redness. Exit site and suture cleansed with normal saline and redressed with dry gauze dressing. Hemovac emptied of 90-mL sanguineous secretions and recompressed.

—A. Smith, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient has a Hemovac drain placed in the left knee following surgery. The record indicates it has been draining serosanguineous secretions, 40 to 50 mL every shift. While performing your initial assessment, you note that the collection chamber is completely expanded. The nurse empties the device and compresses to resume suction. A short time later, the nurse observes that the chamber is completely expanded again:* Inspect the tubing for kinks or obstruction. Inspect the device, looking for breaks in the integrity of the chamber. Make sure the cap is in place and closed. Assess the patient for changes in condition. Remove the dressing and assess the site. Make sure the drainage tubing has not advanced out of the wound, exposing any of the perforations in the tubing. If you are not successful in maintaining the suction, notify the health care team of the findings and interventions and document the event in the patient's record.

SPECIAL CONSIDERATIONS

- A sterile dressing is usually maintained for 24 to 48 hours; the use of a dressing after this time depends on the site assessment and amount of drainage (Orth, 2018). The site may be treated as an additional surgical wound, but often these sites are left open to air 24 hours after surgery. Refer to facility policy and prescribed interventions regarding need for sterile approach to site care and use of dressing.
- When the patient with a drain is ready to ambulate, empty and compress the drain before activity. Secure the drain to the patient's gown below the wound, making sure there is no tension on the drainage tubing. This removes excess drainage, maintains maximum suction, and avoids strain on the drain's suture line.
- Appropriate nutritional support is critical in achieving successful wound healing and may be overlooked (Quain & Khardori, 2015). Collaborate with the registered dietician and dietary staff to develop an individualized nutrition intervention plan for the patient (Baranoski & Ayello, 2020).

Community-Based Care Considerations

- Drain site care in the community setting is a clean, not sterile, procedure. Patients will use soap and water to clean the skin around the drain site (Memorial Sloan Kettering Cancer Center, 2019).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Skill 33-6 Collecting a Wound Culture

DELEGATION CONSIDERATIONS

The collection of a wound culture is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the collection of a wound culture may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- A sterile culture kit (aerobic and/or anaerobic) with swab, or a culture tube with individual sterile swabs
- Sterile gloves
- Clean, disposable gloves
- Additional PPE, as indicated
- Plastic bag or appropriate waste receptacle
- Patient label for the sample tube
- Biohazard specimen bag
- Bath blanket (if necessary to drape the patient)
- Supplies to clean the wound with saline without preservatives (Baranoski & Ayello, 2020) and reapply the prescribed dressing after obtaining the culture. (Refer to Skills 33-2 and 33-3.)

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for prescribed intervention for obtaining a wound culture. Gather necessary supplies. If possible, obtain the wound culture prior to the start of antimicrobial therapy.	Reviewing the health record and care plan validates the correct patient and correct procedure. Preparation promotes efficient time management and an organized approach to the task. Antimicrobial therapy interferes with microorganism growth, so it is important to obtain the wound culture prior to the start of antimicrobial therapy, if possible (Huddleston Cross, 2014; Fischbach & Fischbach, 2018). If obtained after the initiation of antimicrobial therapy, provide information about the name of the antimicrobial, dose, and the date the therapy was initiated to the lab to aid in accurate interpretation of the culture findings (Baranoski & Ayello, 2020).
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.
5. Close the curtains around the bed and close the door to the room, if possible. Explain to the patient what you are going to do and why you are going to do it.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement.
6. Assess the patient for possible need for nonpharmacologic pain-reducing interventions or analgesic medication before obtaining the wound culture. Administer appropriate prescribed analgesic.	Pain is a subjective experience influenced by past experience. Wound care and dressing changes may cause pain for some patients.

Allow enough time for the analgesic to achieve its effectiveness before beginning the procedure.	
7. Place an appropriate waste receptacle within easy reach for use during the procedure.	Having the waste container handy means that soiled materials may be discarded easily, without the spread of microorganisms.
8. Adjust the bed to a comfortable working height (VHACEOSH, 2016).	Having the bed at the proper height prevents back and muscle strain.
9. Assist the patient to a comfortable position that provides easy access to the wound. If necessary, drape the patient with the bath blanket to expose only the wound area. Place a waterproof pad under the wound site. Check the culture label against the patient's identification bracelet (Figure 1).	Patient positioning and the use of a bath blanket provide for comfort and warmth. Checking the culture label with the patient's identification ensures the correct patient and the correct procedure.

FIGURE 1. Checking culture label with the patient's identification band.

10. If there is a dressing in place on the wound, put on clean gloves and carefully remove the dressing. Refer to Skill 33-2. Note the presence, amount, type, color, and odor of any drainage on the dressings. Place soiled dressings in the appropriate waste receptacle.	Gloves protect the nurse from handling contaminated dressings. The dressing must be removed to allow access to the wound.
11. Remove gloves and perform hand hygiene.	Hand hygiene prevents the transmission of microorganisms.
12. Put on gloves. Assess and clean the wound, **using saline that has no preservative** (Baranoski & Ayello, 2020), as outlined in Skills 33-2 and 33-3.	Gloves prevent contact with blood and/or body fluids. This information provides evidence about the wound healing process and/or the presence of infection. Cleaning the wound removes wound exudate, topical therapies, and wound debris, which could introduce extraneous organisms into the collected specimen, resulting in inaccurate results (Baranoski & Ayello, 2020).
13. Dry the skin surrounding the wound with gauze. Put on clean gloves.	Excess moisture can contribute to skin irritation and breakdown. The use of a culture swab does not require immediate contact with the skin or wound, so clean gloves are appropriate to protect the nurse from contact with blood and/or body fluids.
14. Twist the cap to loosen the swab on the Culturette	Supplies are ready to use and within easy reach, and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

tube or open the separate swab(s) and remove the cap from the culture tube. **Keep the swab and inside of the culture tube(s) sterile (Figure 2).**	aseptic technique is maintained.
15. If contact with the wound is necessary to separate wound margins to permit insertion of the swab deep into the wound, put a sterile glove on one hand to manipulate the wound margins. Clean gloves may be appropriate for contact with pressure injuries and chronic wounds.	If contact with the wound is necessary to collect the specimen, a sterile glove is necessary to prevent contamination of the wound. Clean technique may be appropriate for cleaning chronic wounds or pressure injuries (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a).
16. **Identify a 1-cm area of the wound that is free from necrotic tissue.** Carefully insert the swab into this area of clean viable tissue. **Press the swab to apply sufficient pressure to express fluid from the wound tissue and rotate the swab for 5 seconds** (Baranoski & Ayello, 2020)**. Avoid touching the swab to intact skin at the wound edges (Figure 3).**	Cotton tip absorbs wound drainage. This technique (Levine technique) is considered to provide more accurate results and best practice for swab cultures (Baranoski & Ayello, 2020; WOCN, 2016). Contact with skin could introduce extraneous organisms into the collected specimen, resulting in inaccurate results.

FIGURE 2. Removing cap from culture tube.

FIGURE 3. Rotating swab several times over wound surface.

17. Place the swab back in the culture tube (Figure 4). **Do not touch the outside of the tube with the swab.** Secure the cap. Some swab containers have an ampule of medium at the bottom of the tube. It might be necessary to crush this ampule to activate. Follow the manufacturer's instructions for use.	The outside of the container is protected from contamination with microorganisms, and the sample is not contaminated with organisms not in the wound. Surrounding the swab with culture medium is necessary for accurate culture results.
18. Use another swab if collecting a specimen from another area of the wound or site and repeat the procedure.	Using another swab at a different site prevents cross-contamination of the wound.
19. Remove gloves and discard them accordingly. Perform hand hygiene.	Removing gloves properly reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the transmission of microorganisms.
20. Put on gloves. Place a dressing on the wound, as appropriate, based on prescribed interventions and/or the plan of care. Refer to Skill 33-2. Remove gloves. Perform hand hygiene.	Wound dressings protect, absorb drainage, provide a moist environment, and promote wound healing. Removing gloves and performing hand hygiene reduce the risk for transmission of microorganisms and contamination of other items.
21. After securing the dressing, label dressing with date and time. Remove all remaining equipment; place the patient in a comfortable position, with side rails up as indicated and bed in the lowest position.	Recording date and time provides communication and demonstrates adherence to care plan. Proper patient and bed positioning promotes safety and comfort.
22. Label the specimen according to your institution's guidelines. Information included in addition to the	Proper labeling ensures proper identification of the specimen. Specimens must be sent to the laboratory

patient's identification may include wound site, time the specimen was collected, any antimicrobials the patient is receiving, and the identity of the person who obtained the specimen (Baranoski & Ayello, 2020). Send or transport specimen to the laboratory in a biohazard bag immediately or within the optimal time from for transport as indicated by facility policy and guidelines (Figure 5).

FIGURE 4. Placing swab in culture tube.

FIGURE 5. Labeled culture container in biohazard bag.

23. Remove PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Document the location of the wound, the assessment of the wound, including the type of tissue present, presence of necrotic tissue, stage (if appropriate), and characteristics of drainage. Include the appearance of the surrounding skin. Document cleansing of the wound and the obtained culture. Record any skin care and/or dressing applied. Note pertinent patient and family/caregiver education and any patient reaction to this procedure, including patient's pain level and effectiveness of nonpharmacologic interventions or analgesia, if administered.

Sample Documentation

6/22/25 2100 Wound noted on patient's hand: 2 cm × 3 cm × 1 cm, red, tender, with purulent drainage present. Edges macerated, without erythema and tenderness. Wound cleaned with normal saline, culture obtained. Skin protectant/barrier applied to surrounding area, wound redressed with alginate, cover dressing, and roller gauze. Hand elevated. Culture labeled and sent to lab.

—J. Wentz, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *The nurse has inserted the culture swab into the patient's wound to obtain the specimen and realizes that the wound was not cleaned:* Discard this swab. Obtain the additional supplies needed to clean the wound according to facility policy and a new culture swab. Cleaning the wound removes wound exudate, topical therapies, and wound debris, which could introduce extraneous organisms into the collected specimen, resulting in inaccurate results (Baranoski & Ayello, 2020). Clean the wound using a using saline that has no preservative (Baranoski & Ayello, 2020) and then proceed to obtain the culture specimen.
- *As the nurse prepares to insert the culture swab into the wound, the nurse inadvertently touches the swab to the patient's bedclothes or other surface:* Discard this swab, obtain a new culture swab, and collect the specimen.

GENERAL CONSIDERATIONS

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Tissue biopsy is considered the "gold standard" of wound cultures; however, it and the aspiration technique are invasive and are performed by physicians and advanced practice professionals (Baranoski & Ayello, 2020; WOCN, 2016). Swab specimens are more commonly used because they are most easily collected, readily available, and may be collected by nurses in general practice (Baranoski & Ayello, 2020).
- Final culture results may take 24 to 72 hours depending on the method used and organism suspected; antimicrobial therapy based on the pathogens most commonly involved in a particular type of wound may be started immediately and changed if indicated when culture and sensitivity results are available (WOCN, 2016).

Skill 33-7 Applying Negative-Pressure Wound Therapy

DELEGATION CONSIDERATIONS

The application of negative pressure wound therapy is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, the application of negative pressure wound therapy may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Negative pressure unit
- Evacuation/collection canister (depending on specific system in use)
- Wound contact material, as indicated by wound care plan and device/materials in use
- Transparent adhesive drape
- Connection pad/tubing port
- Drainage tubing
- Skin protectant/barrier wipes
- Sterile gauze sponge
- An 18- to 19-gauge needle/angiocath and 30- to 35-mL syringe or a commercial cleanser packaged in a pressurized container (Baranoski & Ayello, 2020, p. 152; McLain & Moore, 2021; WOCN, 2016)
- Sterile irrigation solution as prescribed, warmed to body temperature, commonly 0.9% normal saline solution or other solution as prescribed
- Waste receptacle to dispose of contaminated materials
- Sterile gloves (two pairs)
- Sterile scissors
- Clean, disposable gloves
- Gown, mask, eye protection
- Additional PPE, as indicated
- Sterile scissors
- Waterproof pad and bath blanket

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for prescribed application of NPWT therapy, including the prescribed pressure setting for the device. Gather necessary supplies.	Reviewing the health record validates the correct patient and correct procedure. Preparation promotes efficient time management and an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
3. Identify the patient.	Identifying the patient ensures the right patient receives

	the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of task.
5. Close the curtains around the bed and close the door to the room, if possible. Explain what you are going to do and why you are going to do it to the patient.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement.
6. Assess the patient for possible need for nonpharmacologic pain-reducing interventions or analgesic medication before wound care dressing change. Administer appropriate prescribed analgesic. Allow enough time for the analgesic to achieve its effectiveness before beginning the procedure.	Pain is a subjective experience influenced by past experience. Wound care and dressing changes may cause pain for some patients.
7. Adjust the bed to a comfortable working height (VHACEOSH, 2016).	Having the bed at the proper height prevents back and muscle strain.
8. Assist the patient to a comfortable position that provides easy access to the wound area. Position the patient so the cleaning/irrigation solution will flow from the clean end of the wound toward the dirty end. Expose the area and drape the patient with a bath blanket, if needed. Put a waterproof pad under the wound area.	Patient positioning and draping provide for comfort and warmth. Gravity directs the flow of liquid from the least contaminated to the most contaminated area. Waterproof pad protects the patient and the bed linens.
9. Have the disposal bag or waste receptacle within easy reach for use during the procedure.	Having a waste container handy allows for easy disposal of the soiled dressings and supplies, without the spread of microorganisms.
10. Using sterile technique, prepare a sterile field and add all the sterile supplies needed for the procedure to the field. Pour warmed, sterile irrigating solution into the sterile container, as indicated.	Proper preparation ensures that supplies are within easy reach and sterility is maintained. Warmed solution may result in less discomfort.
11. Put on a gown, mask, and eye protection.	The use of PPE is part of *Standard Precautions*. A gown protects your clothes from contamination if splashing should occur. Goggles protect mucous membranes of your eyes from contact with irrigant fluid.
12. If NPWT is currently in use, turn off the negative pressure unit. Consider turning off suction 5 to 10 minutes before dressing change to reduce pressure (Banasiewicz et al., 2019). Put on gloves. Loosen the tape on the old dressings by removing in the direction of hair growth and the use of a push–pull method (Fumarola et al., 2020). Push–pull method: lift a corner of the dressing away from the skin, and then gently push the skin down and away from the dressing/adhesive (Fumarola et al., 2020). Continue moving fingers of the opposite hand to support the skin as the product is removed (Fumarola et al., 2020). Once all adhesive is loosened from the skin, carefully lift dressing from the surrounding skin to prevent medical adhesive–related skin injury (MARSI). Remove the sides/edges first, then the center. If the patient is at increased risk for MARSI, requires repeated application or removal of adhesive devices, or there is resistance, use an adhesive remover (Banasiewicz et al., 2019; Barton, 2020; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).	Reduction in pressure reduces risk of pain associated with dressing removal (Banasiewicz et al., 2019). Gloves protect the nurse from contaminated dressings and prevent the spread of microorganisms. Removal of the tape in the direction of hair growth minimizes trauma to the skin (Fumarola et al., 2020). Pushing the skin down and away from the adhesive reduces the risk for medical adhesive–related skin injury (MARSI) (Fumarola et al., 2020). The use of adhesive remover allows for the easy, rapid, and painless removal without the associated problems of skin stripping and helps reduce patient discomfort (Banasiewicz et al., 2019; Barton, 2020; Fumarola et al., 2020; Kelly-O'Flynn et al., 2020).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

13. Carefully remove the soiled dressings. If any part of the dressing sticks to the underlying skin, use small amounts of sterile saline to help loosen and remove it.	Cautious removal of the dressing is more comfortable for the patient and ensures that any drain present is not removed. Sterile saline moistens the dressing for easier removal and minimizes damage and pain.
14. Note the presence, amount, type, color, and odor of any drainage on the dressings. **Note the number of pieces of wound contact material removed from the wound. Compare with the documented number from the previous dressing change.**	The presence and characteristics of drainage should be documented. All dressing materials must be removed from the wound bed during NPWT dressing changes (Baranoski & Ayello, 2020). Counting the number of pieces of wound contact material assures the removal of all foam that was placed during the previous dressing change (Schreiber, 2016).
 15. Discard the dressings in the receptacle. Remove your gloves and put them in the receptacle. Perform hand hygiene.	Proper disposal of dressings and used gloves prevents the spread of microorganisms. Hand hygiene prevents the transmission of microorganisms.
16. Put on sterile gloves. Using sterile technique, clean or irrigate the wound, based on wound care plan and prescribed wound care. Alternatively, clean gloves (clean technique) may be used when cleaning a chronic wound or pressure injury.	Aseptic technique maintains sterility of items to come in contact with wound. Cleaning and/or irrigation remove exudate and debris. Clean technique is appropriate for cleaning chronic wounds, wounds in the home, or pressure injuries (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a).
17. Clean the area around the wound with normal saline or prescribed skin cleanser. Dry the surrounding skin with a sterile gauze sponge.	Cleaning of skin removes debris and aids in adherence of dressing materials. Moisture provides a medium for the growth of microorganisms.
18. Assess the wound for appearance, stage, presence of eschar, granulation tissue, epithelialization, undermining, tunneling, necrosis, sinus tract, and drainage. Assess the appearance of the surrounding tissue. Measure the wound.	This information provides evidence about the wound healing process and/or the presence of infection.
 19. Remove gloves and perform hand hygiene.	Hand hygiene prevents the transmission of microorganisms.
20. Put on sterile gloves. **Wipe intact skin around the wound with a skin protectant/barrier wipe and allow it to dry.** Alternatively, clean gloves (clean technique) may be used when cleaning a chronic wound or pressure injury.	Aseptic technique maintains sterility of items to come in contact with wound. Skin barrier/protectant prevents skin irritation and excoriation from tape, adhesives, and wound drainage (Fumarola et al., 2020; Kelly-O'Flynn et al., 2020). Clean technique is appropriate for cleaning chronic wounds, wounds in the home, or pressure injuries (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a).
21. If the use of a wound contact layer (impregnated porous gauze or silicone adhesive contact layer) is indicated, use sterile scissors to cut the wound contact layer to fit the wound bed. Apply wound contact layer to the wound bed.	Impregnated porous gauze or silicone adhesive contact layer may be indicated, depending on wound filler material in use, to prevent adherence of wound filler to wound be to protect the wound bed (McNichol et al., 2022).
22. Fit the wound contact material to the shape of the wound. • If using foam wound contact material, use sterile scissors to cut the foam to the shape and measurement of the wound. **Do not cut foam over the wound.** More than one piece of foam may be	Wound contact material should fill the wound, but not cover intact surrounding skin. Foam fragments may fall into the wound if cutting is performed over the wound. Foam-to-foam contact allows for even distribution of negative pressure. Recording the number of pieces of wound contact material aids in assuring the removal of all dressing material with next

necessary if the first piece is cut too small. Carefully place the foam in the wound (Figure 1). **Ensure foam-to-foam contact if more than one piece is required.**

- **Note the number of pieces of wound filler placed in the wound.**
- **Do not under- or overfill.**

dressing change (Schreiber, 2016). Appropriate filling of wound is necessary to ensure safe and effective application of NPWT (Apelqvist et al., 2017; Schreiber, 2016).

23. Trim and place the transparent adhesive drape or hydrocolloid to cover the wound contact material and an additional 3- to 5-cm border of intact periwound tissue (Figure 2). **Avoid stretching the transparent adhesive drape tight over the wound.**

The occlusive air-permeable adhesive drape or hydrocolloid provides a seal, allowing the application of the negative pressure. Tight stretching of transparent adhesive drape during application may cause periwound damage (Schreiber, 2016).

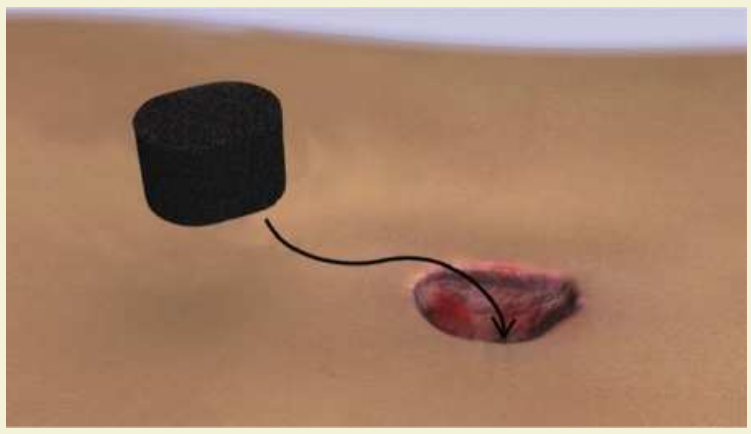


FIGURE 1. Cutting wound contact material (foam) to shape and measurement of wound. (*Source:* Used with permission. Courtesy of KCI, an Acelity Company.)

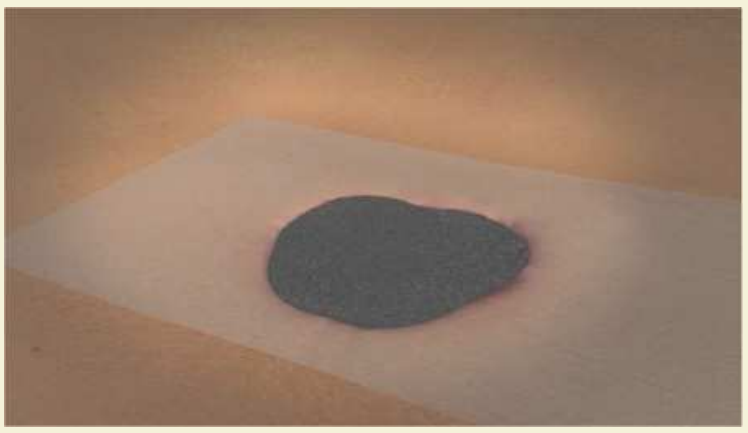

FIGURE 2. Placing transparent adhesive drape to cover the wound. (*Source:* Used with permission. Courtesy of KCI, an Acelity Company.)

24. Apply the connector pad/tubing port, if necessary, depending on the device and dressing materials in use. Choose an appropriate site to apply the connector pad/tubing port. Pinch the transparent adhesive drape and cut a hole through it (Figure 3). Apply the connector pad/tubing port and connective tubing over the hole (Figure 4). Position tubing away from the periwound area and anchor (Schreiber, 2016). Some devices, such as sNPWT, have integrated tubing, tubing port/connector pad and dressing, which do not require separate connection to the dressing.

Position the connector pad/tubing port and tubing to avoid placement over pressure areas, bony prominences, or skin creases to avoid excess pressure on the underlying skin and tissues (Schreiber, 2016). A hole in the drape and application of connector pad/tubing port and connective tubing are necessary for the application of negative pressure and removal of fluid and/or exudate. Securing the tubing prevents accidental excessive tension on the dressing (Schreiber, 2016).

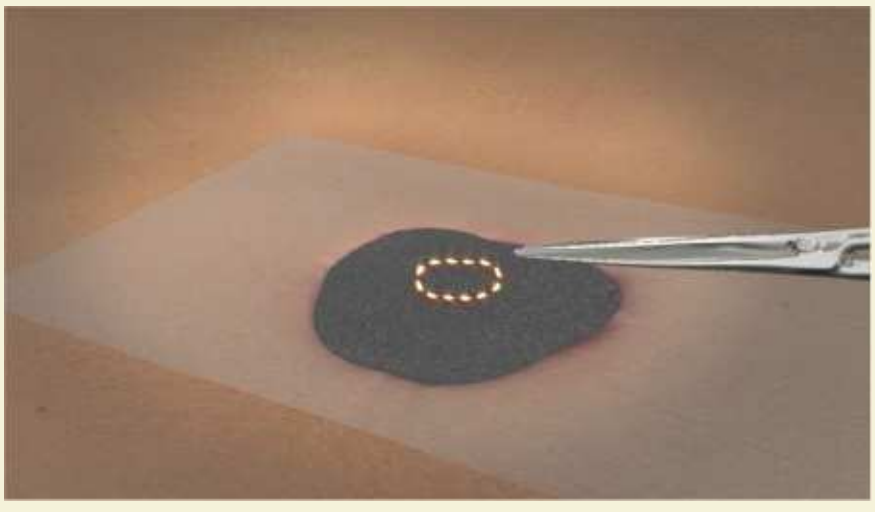

FIGURE 3. Cutting a hole in the drape.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

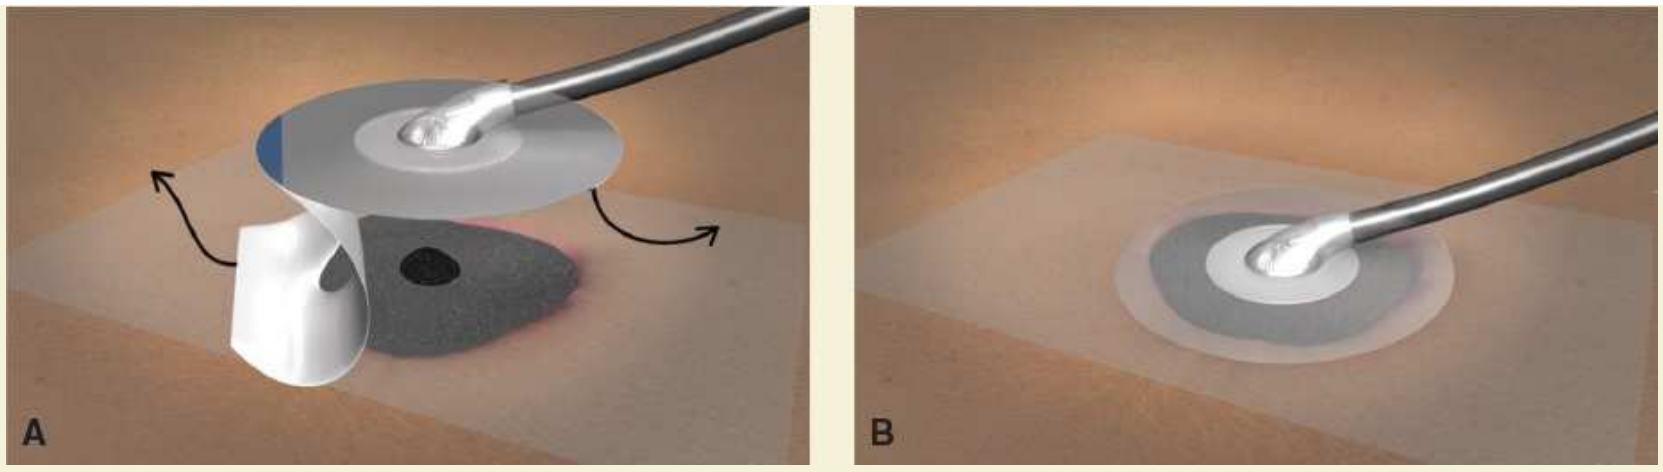

FIGURE 4. Applying the connecting pad over the hole.

25. Attach the drainage cannister, depending on the device in use. Remove the drainage collection canister from the package and insert into the negative pressure unit until it locks into place. Attach the connective tubing to the canister and check that the clamps on the tubing are open, if present.

The tubing and canister provide means for the collection of drainage. Clamps must be open for the device to work properly.

26. Remove gloves and discard. Perform hand hygiene. Turn on the power to the negative pressure unit. Select the prescribed therapy settings (suction and cycle type) and start the device.

Removal of gloves, proper disposal, and hand hygiene prevent transmission of microorganisms.

27. **Assess the dressing to ensure seal integrity. The dressing should be collapsed, shrinking to the wound contact material and skin (Figure 5). Observe drainage in tubing.**

Shrinkage confirms a good seal, allowing for accurate application of pressure and treatment. Observation of drainage in device tubing ensures proper flow (Schreiber, 2016).

FIGURE 5. Dressing is collapsed, shrinking to wound contact material and skin. (*Source:* Used with permission. Courtesy of KCI, an Acelity Company.)

28. Label dressing with date and time. Remove all remaining equipment; place the patient in a comfortable position, with side rails up as indicated and bed in the lowest position.

Recording the date and time provides communication and demonstrates adherence to the care plan. Proper patient and bed positioning promotes safety and comfort.

29. Remove PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

30. Check all wound dressings at least every shift. More frequent checks may be needed if the wound is more. Check negative pressure settings at least every shift. Assess the patient's tolerance of and response to the therapy at least every shift.

Checking dressings, the device, and patient response ensures the assessment of changes in patient condition and timely intervention to prevent complications.

DOCUMENTATION

Guidelines

Record your assessment of the wound, including evidence of granulation tissue, stage (if appropriate), and characteristics of drainage. Include the appearance of the surrounding skin. Document the cleansing or irrigation of the wound and solution used. Document the application of the NPWT, noting the pressure setting, patency, and seal of the dressing. Describe the color and characteristics of the drainage in the collection chamber. Record pertinent patient and family/caregiver education and any patient reaction to this procedure, including the presence of pain and effectiveness or ineffectiveness of pain interventions.

Sample Documentation

4/5/25 0800 NPWT dressing intact with good seal maintained, system patent, pressure setting 80 mm Hg. Purulent, sanguineous drainage noted in collection chamber and tubing. Surrounding tissue without edema, redness, ecchymosis, or signs of irritation. Patient verbalizes an understanding of use of the device and movement limitations related to the system.

—B. Clark, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *While assessing the patient, the nurse notes that the seal between the transparent adhesive drape and the wound contact material and skin is not tight:* Check the dressing seals, tubing connections, and canister insertion, and ensure the clamps are open. If a leak in the transparent drape is identified, the appropriate pressure is not being applied to the wound. Apply additional transparent dressing to reseal. If this application does not correct the break, change the dressing.
- *Patient reports acute pain while NPWT is operating:* Assess the patient for other symptoms, obtain vital signs, assess the wound, and assess the vacuum device for proper functioning. Report your findings to the health care team and document the event in the patient's health record. Administer analgesics, as prescribed. Continue or change the wound therapy, as prescribed. Some patients may be unable to tolerate NPWT and may require a change in the type of wound contact material used, addition of a wound contact layer, intermittent therapy cycling, a reduction in suction pressure, or discontinuation of the therapy (Apelqvist et al., 2017; Milne, 2015; Schreiber, 2016).

SPECIAL CONSIDERATIONS

- The wound should be debrided of as much necrotic tissue as possible before using NPWT; it is best to have the wound bed free of necrotic tissue (Baranoski & Ayello, 2020).
- Time dressing changes to allow for wound assessment by other members of the health care team.
- Dressings may need to be changed more often than 48 to 72 hours for wounds with heavy exudate (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a).
- Measure and record the amount of drainage each shift as part of the intake and output record.
- Check the fluid level in the canister periodically. Depending on the particular device in use, replace the canister whenever full or nearly full.
- The battery pack for sNPWT devices may contain a magnet; these devices should be kept at least 4 inches away from other medical devices to avoid disruption of nearby medical devices (Smith & Nephew, Inc., 2018; Watret et al., 2020).
- Be alert for audible and visual alarms on the vacuum device to alert you to problems, such as tipping of the device greater than 45 degrees, a full collection canister, an air leak in the dressing, or dislodgement of the canister.
- NPWT should operate for 24 hours a day. It should not be shut off for more than 2 hours in a 24-hour period. Remove the dressing any time therapy cannot be reestablished within the 2-hour time period (McNichol et al., 2022). When suction is lost, there is no mechanism for exudate control and allowing the dressing to remain in place without suction significantly increases the risk of wound infection (McNichol et al., 2022, p. 226). When NPWT is restarted, clean/irrigate the wound as prescribed or per facility policy and apply a new NPWT dressing.
- When maceration of the surrounding skin beneath the occlusive dressing occurs, this may be treated by placing a barrier/wafer dressing beneath the transparent dressing to protect the skin. Verify with facility policy, as needed.
- Approaches to NPWT continue to change, including the size of the vacuum pumps, types of wound contact materials and length of time recommended for the use of NPWT (Benbow, 2016).
- Appropriate nutritional support is critical in achieving successful wound healing and may be overlooked (Quain & Khardori, 2015). Collaborate with the registered dietician and dietary staff to develop an individualized nutrition

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

intervention plan for the patient (Baranoski & Ayello, 2020).

Community-Based Care Considerations

- NPWT can be used in outpatient and home and other community settings (Edwards et al., 2018; EPUAP, NPIAP, & PPPIA, 2019a).
- Patients and caregivers must be educated about NPWT: how NPWT works, the risks and benefits of NPWT, device operation, signs of and actions for possible complications, response to alarms and emergencies, and when to seek and who to contact for assistance (Benbow, 2016; Schreiber, 2016).

Skill 33-8 Applying an External Heating Pad

DELEGATION CONSIDERATIONS

The application of an external heating pad may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Aquathermia heating pad with electronic unit
- Distilled water
- Cover for the pad, if not part of pad
- Gauze bandage or tape to secure the pad
- Bath blanket
- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for prescribed intervention for the application of heat therapy, including frequency, type of therapy, body area to be treated, and length of time for the application. Gather necessary supplies.	Reviewing the health record and care plan validates the correct patient and correct procedure. Preparation promotes efficient time management and an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of task.
5. Close the curtains around the bed and close the door to the room if possible. Explain what you are going to do and why you are going to do it to the patient.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement.
6. Adjust the bed to a comfortable working height (VHACEOSH, 2016).	Having the bed at the proper height prevents back and muscle strain.
7. Assist the patient to a comfortable position that provides easy access to the area where the heat will be applied; use a bath blanket to cover any other exposed area.	Patient positioning and the use of a bath blanket provide for comfort and warmth.

8. Assess the condition of the skin where the heat is to be applied.	Assessment supplies baseline data for posttreatment comparison and identifies conditions that may contraindicate the application.
9. Check that the water in the electronic unit (Figure 1) is at the appropriate level. Fill the unit two thirds full or to the fill mark, with distilled water, if necessary. Check the temperature setting on the unit to ensure it is within the safe range.	Sufficient water in the unit is necessary to ensure proper function of the unit. Tap water leaves mineral deposits in the unit. Checking the temperature setting helps to prevent skin or tissue damage.

FIGURE 1. External heating pad electronic unit.

10. Attach pad tubing to the electronic unit tubing (Figure 2).	Allows flow of warmed water through the heating pad.
11. Plug in the unit and warm the pad before use. Apply the aquathermia pad to the prescribed area (Figure 3). Secure with roller gauze or tape.	Plugging in the pad readies it for use. Heat travels by conduction from one object to another. Gauze bandage or tape holds the pad in position; **do not use pins, as they may puncture and damage the pad.**

FIGURE 2. Attaching pad tubing to electronic unit tubing.

FIGURE 3. Applying heating pad to the prescribed area.

 12. Remove PPE, if used, and perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
13. **Monitor the condition of the skin and the patient's response to the heat at frequent intervals, according to facility policy. Do not exceed the prescribed length of time for the application of heat.**	Maximum **vasodilation** and therapeutic effects from the application of heat occur within 20 to 30 minutes. Using heat for more than this amount of time results in tissue congestion and **vasoconstriction**, known as the rebound phenomenon. Prolonged heat application may also result in an increased risk of burns and tissue damage. Assessment of the patient's skin is necessary for early detection of adverse effects, thereby allowing prompt intervention to avoid complications.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

14. After the prescribed time for the treatment (up to 20 to 30 minutes) (Cleveland Clinic, 2020; Klein, 2019) remove the aquathermia pad. **Do not exceed the prescribed amount of time.** Reassess the patient and area of application, noting the effect and presence of any adverse effects.	Using heat for more than this amount of time results in tissue congestion and vasoconstriction, known as the rebound phenomenon. Prolonged heat application may also result in an increased risk of burns and tissue damage. Assessment provides input as to the effectiveness of the treatment.
15. Remove all remaining equipment; place the patient in a comfortable position, with side rails up as indicated and bed in the lowest position.	Proper patient and bed positioning promotes safety and comfort.
 16. Remove additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Document the rationale for application of heat therapy. If the patient is receiving heat therapy for pain, document the assessment of pain pre- and postintervention. Specify the type of heat therapy and location where it is applied as well as the length of time applied. Record the condition of the skin, noting any redness or irritation before the heat application and after the application. Document the patient's reaction to the heat therapy. Record any appropriate patient or family/caregiver education.

Sample Documentation

9/13/25 2300 Patient states he has lower back pain, rating it 5 of 10, constant and aching. Aquathermia pad applied to patient's lower back for 30 minutes; patient now rating pain as 2 of 10 and intermittent. Skin without signs of redness or irritation before and after application.

—M. Martinez, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *When performing a periodic assessment of the site during the application of heat, the nurse notes excessive swelling and redness at the site and the patient reports pain that was not present prior to the application of heat:* Remove the heat source. Assess the patient for other symptoms and obtain vital signs. Report your findings to the health care team and document the assessment and related interventions in the patient's record. Complete a variance or occurrence report, based on facility policy and procedures, to document the occurrence of an event that is out of the ordinary that has the potential to result in harm.

SPECIAL CONSIDERATIONS

General Considerations

- Direct heat treatment may be contraindicated for patients at risk for bleeding, patients with a sprained limb in the acute stage, or patients with a condition associated with acute inflammation (Klein, 2019). Use cautiously with children and older adults. Patients with diabetes, stroke, spinal cord injury, and peripheral neuropathy are at risk for thermal injury, as are patients with very thin or damaged skin. Be extremely careful when applying to heat-sensitive areas, such as scar tissue and stomas.
- Instruct the patient not to lean or lie directly on the heating device, as this reduces air space and increases the risk of burns.
- Check the water level in the aquathermia unit periodically. Evaporation may occur. If the unit runs dry, it could become damaged. Refill with distilled water periodically.

Older Adult Considerations

- Older adults are more at risk for skin and tissue damage because of their thin skin, loss of heat sensation, decreased subcutaneous tissue, and changes in the body's ability to regulate temperature (Eliopoulos, 2018; Touhy & Jett, 2018). Check these patients more frequently during therapy.

Community-Based Care Considerations

- A hot water bag or commercially prepared hot pack may be used in the home to apply heat. If using a hot water bag, fill with hot tap water to warm the bag, then empty it to detect any leaks. Check the temperature of the water with a thermometer or test on your inner wrist, adjusting the temperature as prescribed. Water used for heat applications needs to be at the appropriate temperature to avoid skin damage: set the temperature of the water within a range of 105° to 109°F (40.5° to 43°C), which is considered to be physiologically effective and comfortable for the patient. **Water temperature should not exceed 120°F (49°C)** (International Association of Fire Fighters, n.d.). Fill the bag one-half to two thirds full. Partial filling keeps the bag lightweight and flexible so that it can be molded to the treatment area. Squeeze the bag until the water reaches the neck; this expels air, which would make the bag inflexible and would reduce heat conduction. Fasten the top and cover the bag with an absorbent cloth. The covering protects the skin from direct contact with the bag. If using a commercially prepared hot pack, follow the manufacturer's directions and carefully assess skin before and after heat application.
- Electric heating pads may be used in the home to apply heat. Avoid the use of pins to prevent electric shocks. Use a dry covering over the pad to protect skin. Place a heating pad anteriorly or laterally to, not under, the body part. If the heating pad is between the patient and the mattress, heat dissipation may be inadequate, leading to burning of the patient or the bed linens. Caution the patient to use a heating pad with a selector switch that cannot be turned up beyond a safe temperature. The patient's receptors adapt to the initial application of heat, the patient may attempt to inappropriately increase the heat because the pad does not seem sufficiently warm, with the potential for burns.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Work through the Evolving Case Study 33-1 to help develop your clinical reasoning and clinical judgment skills.
. Review the Concept Map for Lucius Everly. Pay special attention to the interventions that address more than one actual or potential problem.
. How would you individualize your teaching about needed supplies, wound care, and resources for the following patients?

- A man who is currently unhomed admitted to the hospital for gangrene of the big toe; the toe has been amputated
- A teenage gang member treated in the emergency department for a superficial (but long) knife wound
- An infant who has had abdominal surgery and is now having diarrhea
- A frail, 80-year-old man who needs daily dressing changes on a draining wound and lives with his wife who happens to be blind

. Describe the nursing interventions you would include in a care plan to prevent pressure injuries in the following patients:

- A middle-aged person, 70 lb over normal body weight, who has a fractured femur and is recovering at home (they live alone)
- A 90-year-old man with cognitive impairment who is confined to bed
- A 17-year-old girl who is paralyzed from the waist down after a diving accident and is wheelchair dependent

EVOLVING CASE STUDY 33-1

Scenario: Sam Bentz, a 56-year-old admitted to the hospital for management of nonhealing wounds and an infection mentions, "Last time I was here, my skin got really irritated and I developed several skin wounds."

QUESTION r/t CUES: Based on the patient's reason for admission, what initial question is the most important for the nurse to ask?

A. "Can you tell me about your wounds and what prompted you to come to the hospital?"
B. "Can you tell me why you were here for your last admission?"
C. "Is this admission due to your lack of follow-through after your last discharge?"
D. "Can you define irritated for me? Was this your interpretation or your provider's?"

Scenario: You note that Sam is 5 ft 4 in tall and weighs more than 300 lb with a BMI of >51.5, which means Sam falls into the obese category for adults of that same height. When you ask Sam to describe the wounds, including their size, location, and anything else they remember, Sam changes the subject and asks when dinner will be delivered.

QUESTION r/t ANALYZING CUES: What can the nurse determine from Sam's response?

A. Sam would benefit from a psychiatric consult to explore their issues.
B. Sam is dodging and is likely to be nonadherent with the treatment plan.
C. Sam is hesitant to talk about their wounds and may benefit from additional support.
D. Sam has a knowledge deficit and needs detailed information about their plan of care.

Scenario: The nurse sits down next to Sam, reframes, and asks the question again. Sam apologizes for reacting and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

admits that they felt "judged and fat-shamed" their last admission. Sam relaxes and begins describing their nonhealing wounds. Seizing the opportunity, the nurse performs an assessment and finds Sam's legs to be edematous, red, and macerated; weeping serous fluid; rough; and painful to the touch. There are also three large, round, deep, yellow, necrotic nonhealing wounds on the left lower leg near the ankle. When the nurse turns Sam to the side, the nurse notes a large, foul-smelling sacral wound that is covered with what appears to be an old duoderm dressing.

QUESTION r/t PRIORITIZING HYPOTHESIS: Based on the objective and subjective assessment of this patient, which priority problem should the nurse identify to guide the plan of care?

A. Altered skin integrity based on the nonhealing, chronic wounds
B. Bathing/hygiene ADL deficit based on the rash in the skin folds
C. Chronic low self-esteem based on their expression of feelings
D. Grief based on the likely role changes that occur with chronic issues

Scenario: The nurse reviews Sam's laboratory and diagnostic results and checks the medication administration record. The nurse sees that Sam has been prescribed a potent antibiotic to treat the diagnosed infection that has moved to the bone (osteomyelitis) and a topical antifungal to manage the severe dermatitis and skin breakdown in the abdominal skin folds.

QUESTION r/t GENERATING SOLUTIONS: The nurse has 10 minutes before having to leave the room and administer blood to another patient. Which intervention is the priority for Sam?

A. Sitting quietly with Sam
B. Contacting Sam's partner and providing an update
C. Consulting wound care for a thorough assessment
D. Hanging the prescribed antibiotic

Scenario: Once the plan of care has been enacted to treat the immediate infection and existing wounds, the nurse moves to consider prevention.

QUESTION r/t TAKING ACTION: What interventions are most likely to be effective in engaging Sam in their treatment and prevention plan? Select all that apply.

A. Having Sam perform a return demonstration on active range of motion and repositioning
B. Facilitating the interaction with the wound care specialist and reinforcing any teaching points
C. Involving Sam's partner (with Sam's permission) in the dressing changes to increase their confidence before discharge
D. Providing a pressure-relief support surface for the bed and chair that Sam agrees to use
E. Instructing Sam on how to use the call bell and television remote in the room

Scenario: After 3 days of antibiotics, Sam is slated for discharge with ongoing home health care visits.

QUESTION r/t EVALUATING OUTCOMES: How will the nurse and Sam know that the treatment plan has been effective? Select all that apply.

A. The current wounds become smaller and show signs of healing.
B. Sam only occasionally has a fever and other signs of infection.
C. Sam is satisfied with the plan and expresses understanding and adherence.
D. Sam's partner can identify the early signs and symptoms of infection.
E. Sam can walk a mile without getting short of breath.

PRACTICING FOR NCLEX

. Thirty-six hours after having surgery, a patient has a slightly elevated body temperature and generalized malaise as well as pain with redness at the surgical site. Which action is most appropriate?
MAR
- Acetaminophen 650 mg every 6 hours prn fever
- Cefazolin (antibiotic) 1 g 1 hour preoperatively
- Cefazolin 1 g, every 6 hours 3 times, postoperatively

a. Documenting the findings and continuing to monitor the patient
b. Administering antipyretics and contacting the provider for an antibiotic prescription
c. Increasing the frequency of assessment to every hour and notifying the patient's primary care provider
d. Obtaining a wound culture and increasing the frequency of wound care

. A nurse on a surgical unit has assessed and documented a patient's wound and drainage. Which statements most accurately describe the characteristic of the wound drainage?
Graphic Record
- T 99.9 P100 RR 20 BP 138/88

- Nursing note: Patient postoperative day 2. Dry sterile dressing changed on abdominal incision. Incision edges are well approximated with a slight ½-cm opening at inferior edge; incisional edges reddened. Hemovac draining sanguineous material, 60 mL for the shift. Patient reports moderate pain, relieved by oxycodone X1.

a. Sanguineous drainage is composed of the clear portion of the blood and serous membranes.
b. Sanguineous drainage is composed of a large number of red blood cells and looks like blood.
c. Sanguineous drainage is composed of white blood cells, dead tissue, and bacteria.
d. Sanguineous drainage is thin, cloudy, and watery and may have a musty or foul odor.

. A postoperative patient who has a large abdominal incision suddenly calls out for help, shouting, "Something is falling out of my incision!" The nurse notes the wound is gaping open with tissue bulging outward. Place the nursing interventions in the order they should be performed, arranged from first to last.

a. Notify the health care provider of the situation.
b. Cover exposed tissue with sterile towels moistened with sterile 0.9% sodium chloride solution.
c. Place the patient in the low Fowler position.
d. Document the findings and outcome of interventions.
e. Maintain NPO status for return to the OR for repair.

. A patient was in an automobile accident and received a wound across the nose and cheek. After surgery to repair the wound, the patient says, "I am so ugly now." Based on this statement, psychosocial problem will the nurse plan to address?

a. Pain
b. Wound healing
c. Body image
d. Change in cognition

. A patient is admitted with a nonhealing surgical wound. Which nursing interventions will the nurse use to promote wound healing? Select all that apply.

a. Applying sterile dressing supplies
b. Discussing zinc supplementation with the health care provider
c. Maintaining bedrest
d. Performing careful hand hygiene
e. Teaching the patient to increase protein in the diet
f. Suggesting the patient consume vitamin C–containing foods.

. A nurse on a surgical unit is working with a nursing student and discussing various phases of wound healing for postoperative patients. Which statements accurately describe these stages? Select all that apply.

a. Hemostasis occurs immediately after the initial injury.
b. A liquid called exudate is formed during the proliferation phase.
c. White blood cells move to the wound in the inflammatory phase.
d. Granulation tissue forms in the inflammatory phase.
e. During the inflammatory phase, the patient has generalized body response.
f. A scar forms during the proliferation phase.

. The nurse preceptor is supervising a new graduate nurse as they assess a patient with a pressure injury. The graduate nurse documents the presence of biofilm in the wound. The preceptor recognizes the graduate nurse understands this concept when the graduate makes which of these statements? Select all that apply.

a. Enhanced healing occurs due to the presence of sugars and proteins.
b. Delayed healing develops due to dead tissue present in the wound.
c. Antibiotics against the bacteria become less effective.
d. Skin loses its integrity due to overhydration of the cells of the wound.
e. Delayed healing due to cells dehydrating and dying occurs.
f. Decreased effectiveness of the patient's normal immune process results.

. The nurse is cleaning an open abdominal wound that has edges that are not approximated. What are accurate steps in this procedure? Select all that apply.

a. Use standard precautions or transmission-based precautions when indicated.
b. Moisten a sterile gauze pad or swab with the prescribed cleansing agent and squeeze out excess solution.
c. Clean the wound in full or half circles beginning on the outside and working toward the center.
d. Work outward from the incision in lines that are parallel to it from the dirty area to the clean area.
e. Clean to at least 1 inch beyond the end of the new dressing if one is being applied.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

f. Clean to at least 3 inches beyond the wound if a new dressing is not being applied.

. A nurse is developing a care plan for an older adult patient who is recovering from a hip arthroplasty (hip replacement). Which assessment findings indicate a high risk for this patient to develop area(s) of pressure injury? Select all that apply.

a. The patient takes time to think about responses to questions.
b. The patient is an older adult with a poor appetite.
c. The patient reports inability to control their urine.
d. The patient's albumin level is <3.2 mg/dL (normal, 3.4 to 5.4 g/dL).
e. Lab findings include BUN 12 (older adult, normal 8 to 23 mg/dL) and creatinine 0.9 (adult female, normal 0.61 to 1 mg/dL).
f. The patient reports increased pain in right hip when repositioning in bed or chair.

. A nurse is explaining to a patient the anticipated effect of the application of cold to an injured area. What response indicates that the patient understands the explanation?

a. "There will be more discomfort in the area where the cold is applied."
b. "I should expect more drainage from the incision after the ice has been in place."
c. "Redness and swelling should decrease after cold treatment."
d. "My incision may bleed more when the ice is first applied."

. A nurse is providing education to a patient and their family regarding the use of negative pressure wound therapy (NPWT). The nurse documents that the teaching has been effective when the patient and family make which statement?

a. "This therapy is used to collect excess blood loss and prevent formation of a scab."
b. "The suction created will prevent infection and promote wound healing with less scar tissue."
c. "Suction stimulates blood flow to the wound, removes excess fluid, and promotes a moist environment for healing."
d. "This treatment irrigates the wound, suctions the irrigation fluid from the wound, and keeps it free from debris wound exudate."

. After an initial skin assessment, the nurse documents the presence pressure area that is reddened and has a 1-cm blister. How will the nurse document the wound stage?

a. Stage 1 dark maroon wound, skin intact
b. Stage 2 with 1-cm blister noted
c. Stage 3 wound base with red granulation tissue
d. Stage 4 blanchable reddened area, 2 cm

. A nurse notes a pressure wound base is red. Using the RYB system for documentation, what intervention is indicated?

a. Irrigating the wound and applying an absorbent dressing
b. Gently cleansing the wound and applying a moist dressing
c. Discussing consultation for surgical debridement with the provider
d. Performing frequent dressing changes to keep the wound and dressing dry

. A nurse is developing education for nurses and UAPs related to prevention of pressure injuries for residents in a long-term care facility. Which action to prevent pressure injury will the nurses delegate to the UAP?

a. Maintaining the head of the bed elevated consistently
b. Massaging over bony prominences
c. Repositioning bedbound patients every 4 hours
d. Using a mild cleansing agent when cleansing the skin

. A nurse caring for a patient with a stage 3 pressure wound with tunneling. How will the nurse best assess the tunneled area?

a. Moisten a sterile, flexible applicator with saline and insert it gently into the wound at a 90-degree angle with the tip down.
b. Photograph the wound per policy and describe the estimated depth in centimeters.
c. Gently insert a sterile applicator into the wound and move it in a clockwise direction.
d. Insert a calibrated probe gently into the wound and mark the point that is even with the surrounding skin surface.

. Determine the patient's risk for pressure injury using the Braden scale found in Figure 33-7, based on information in the electronic health record (EHR).
EHR 1430 Admission Assessment
S: Patient admitted from nursing home for sepsis, confusion, ambulatory dysfunction.
B: 87-year-old patient, with history of heart failure and hypertension; comes to ED with shortness of breath and

yellow sputum.
A: Lungs with crackles, pale, short of breath on exertion, pulse oximetry 88%, skin fragile.
Bedrest maintained. States has not eaten nor drank fluids for last 36 hours; incontinent of small amount of urine × 2.
Responding to painful stimuli, not participating in turning or care.
R: Need orders for oxygen, sputum culture, activity level. Consider IV fluids. J. Smith RN.

a. No risk
b. Moderate risk
c. High risk
d. Very high risk

. The nurse is caring for a patient 1 day postoperative abdominal surgery. The nurse identifies the patient is at risk for wound dehiscence. What patient risk factor is consistent with development of this problem?

a. Cigar smoker
b. Wound drainage 120 mL over 24 hours
c. Height, 5′ 6″ and weight 240 lb
d. WBC count 9,500 c/mm^3

ANSWERS WITH RATIONALES

. **a.** The assessment findings are normal for this stage of healing following surgery. The patient is in the inflammatory phase of the healing process, which involves a response by the immune system. This acute inflammation is characterized by pain, heat, redness, and swelling at the site of the injury (surgery, in this case). The patient also has a generalized body response, including a mildly elevated temperature, leukocytosis, and generalized malaise.

. **b.** Sanguineous drainage consists of large numbers of red blood cells and looks like blood. Bright-red sanguineous drainage is indicative of fresh bleeding, whereas darker drainage indicates older bleeding. Serous drainage, generally watery, is composed primarily of the clear, serous portion of the blood and serous membranes. Purulent drainage is made up of white blood cells, liquefied dead tissue debris, and both dead and live bacteria. It is thick, often has a musty or foul odor, and varies in color (such as dark yellow or green), depending on the causative organism.

. **c, b, a. e. d.** The correct order of nursing interventions for this postoperative emergency is to place the patient in the low Fowler position (to prevent further damage or protrusion from increased intraabdominal pressure), cover exposed tissue with sterile towels moistened with sterile 0.9% sodium chloride solution (to protect the viscera), and notify the health care provider of the situation (to address the issue, likely with surgery). The patient is kept NPO, as prompt surgical repair will be needed. After the patient has received attention, the nurse documents all assessments and interventions in a timely manner.

. **c.** Wounds cause emotional as well as physical stress.

. **a, b, d, e, f.** Careful hand washing (medical asepsis) is the most important. The nurse will use sterile dressings and supplies and promote intake of vitamins, zinc, and protein. Depending on the site of the wound and condition of the patient, bedrest may be indicated.

. **a, c, e.** Hemostasis occurs immediately after the initial injury, and exudate occurs in this phase as plasma and blood components leak out into the injured area. White blood cells, predominantly leukocytes and macrophages, move to the wound in the inflammatory phase to ingest bacteria and cellular debris. During the inflammatory phase, the patient has a generalized body response, including a mildly elevated temperature, leukocytosis (increased number of white blood cells in the blood), and generalized malaise. New tissue, called granulation tissue, forms the foundation for scar tissue development in the proliferation phase. New collagen continues to be deposited in the maturation phase, which forms a scar.

. **c, f.** Wound biofilms are the result of wound bacteria growing in clumps, embedded in a thick, self-made, protective, slimy barrier of sugars and proteins. This barrier contributes to decreased effectiveness of antibiotics against the bacteria (antibiotic resistance) and decreases the effectiveness of the normal immune response by the patient (Baranoski & Ayello, 2020). Necrosis (dead tissue) in the wound delays healing. Maceration or overhydration of cells related to urinary and fecal incontinence can lead to impaired skin integrity. Desiccation is the process of drying up, in which cells dehydrate and die in a dry environment.

. **a, b, e.** The correct procedure for cleaning an open wound with edges that are not approximated is: (1) use standard precautions and appropriate transmission-based precautions when indicated, (2) moisten sterile gauze pad or swab with prescribed cleansing agent and squeeze out excess solution, (3) use a new swab or gauze for each circle, (4) clean the wound in full or half circles beginning in the center and working toward the outside, (5) clean to at least 1 inch beyond the end of the new dressing, and (6) clean to at least 2 inches beyond the wound margins if a dressing is not being applied.

. **b, c, d, f.** Pressure, friction, and shear, as well as other factors, usually combine to contribute to pressure injury development. The skin of older adults is more susceptible to injury; incontinence contributes to prolonged moisture on the skin, as well as negative effects related to urine in contact with skin; hip surgery involves decreased mobility

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

during the postoperative period, as well as pain with movement, contributing to immobility; and increased pain in the hip may contribute to increased immobility. A low albumin level signals a risk for poor wound healing related to malnutrition. Apathy, confusion, and/or altered mental status are risk factors for pressure injury development; however, taking time to formulate responses is consistent with normal aging. This patient's BUN and creatinine are within normal range; however, dehydration (indicated by an elevated BUN and creatinine) is a risk for pressure injury development.

. **c.** The local application of cold constricts peripheral blood vessels, reduces muscle spasms, and promotes comfort. Cold reduces blood flow to tissues, decreases the local release of pain-producing substances, decreases metabolic needs, and capillary permeability. The resulting effects include decreased edema, coagulation of blood at the wound site, promotion of comfort, decreased drainage from wound, and decreased bleeding.

. **c.** Negative pressure wound therapy (NPWT) promotes wound healing and wound closure through the application of uniform negative pressure on the wound bed, reduction in bacteria in the wound, and the removal of excess wound fluid, while providing a moist wound healing environment. The negative pressure results in mechanical tension on the wound tissues, stimulating cell proliferation, blood flow to wounds, and the growth of new blood vessels. It is used to treat a variety of acute or chronic wounds, wounds with heavy drainage, wounds failing to heal, or healing slowly.

. **b.** A stage 2 pressure injury involves partial-thickness loss of dermis and presents as a shallow open ulcer with a red–pink wound bed, without slough. It may also present as an intact or open/ruptured serum-filled blister. Dark maroon or purple wounds with intact skin represent deep tissue injury. Red granulation tissue is present in stage 3 or 4 pressure injuries that are healing. A blanchable, red area is a stage 1 pressure injury.

. **b.** Red wounds are in the proliferative stage of healing and reflect the color of normal granulation tissue. Wounds in this stage need protection with nursing interventions that include gentle cleansing, use of moist dressings, and dressing changes only when necessary (or based on product manufacturer's recommendations). To cleanse yellow wounds, nursing interventions include the use of wound cleansers and irrigation. The eschar found in black wounds requires debridement (removal) before the wound can heal.

. **d.** To prevent pressure injuries, the nurse teaches the UAP to cleanse the skin routinely and whenever soiling occurs by using a mild cleansing agent with minimal friction, and avoiding hot water. The nurse educates the UAP to minimize the effects of shearing force by limiting the amount of time the head of the bed is elevated, when possible. Bony prominences should not be massaged, and bed-bound patients should be repositioned every 2 hours.

. **a.** To measure the depth of a wound, the nurse should perform hand hygiene and apply gloves; moisten a sterile, flexible applicator with saline and insert it gently into the wound at a 90-degree angle with the tip down; mark the point on the swab that is even with the surrounding skin surface, or grasp the applicator with the thumb and forefinger at the point corresponding to the wound's margin; and remove the swab and measure the depth with a ruler.

. **d.** The patient is at very high risk for pressure injury. This patient responds only to painful stimulate (1); is occasionally moist (3); is bedridden (1); has not eaten (1), and requires maximum assistance for moving (1) for a total of 7 points. The Braden scale scoring is: a score of 19 to 23 indicates no risk; 15 to 18, mild risk; 13 to 14, moderate risk; 10 to 12, high risk; and 9 or lower, very high risk (Braden & Maklebust, 2005). In addition, nurses use clinical judgment to incorporate risk factors and/or other health problems into preventative interventions.

. **a.** Wound dehiscence is the partial or total separation of wound layers as a result of excessive stress on unhealed wounds. Patients at greater risk include obese or malnourished individuals; tobacco smokers; and those taking anticoagulants, who have infected wounds, or who experience excessive coughing, vomiting, or straining (Hinkle & Cheever, 2018). An increase in the flow of (serosanguineous) fluid from the wound between postoperative days 4 and 5 may be a sign of an impending dehiscence. The patient may say that "something has suddenly given way."

Activity

Quan Hong Nguyen

Mr. Nguyen is a 75-year-old man who had an ischemic stroke (cerebrovascular accident or brain attack) secondary to thrombosis (formation of a blood clot). His neurologic deficits have remained unchanged for the 2 days he has been in the hospital. He is alert but has hemiplegia (weakness) on his left side. His wife states, “It will be quite a bit of work for me to care for Quan at home. My bones and joints hurt all the time. He needs a lot of help turning, moving, and getting out of bed. How will I manage?”

Kelsi Lester

Kelsi is a 10-year-old girl in the pediatric unit as a result of a skiing accident. Unconscious at the present time, she may or may not regain consciousness. Kelsi is on bedrest. She requires frequent positioning to maintain correct body alignment as well as passive range-of-motion exercises to maintain her range of motion.

Maggie Wyatt

Maggie, a woman in her 30s, was hospitalized because the external fixation device used to treat her fractured right tibia caused an infection in her leg. Following therapy for the infection, the patient is being

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

discharged and requires transfer from the wheelchair to her mother's car.

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Describe the role of the skeletal, muscular, and nervous systems in the physiology of movement.
. Identify variables that influence body alignment and mobility.
. Differentiate isotonic, isometric, and isokinetic exercises.
. Describe the effects of exercise and immobility on major body systems.
. Assess body alignment, mobility, and activity tolerance, using appropriate interview and assessment skills.
. Diagnose actual and potential health problems and needs related to mobility that may be addressed through nursing intervention.
. Utilize principles of ergonomics when appropriate.
. Use safe patient handling and mobility techniques and equipment when positioning, moving, lifting, and ambulating patients.
. Develop exercise programs.
. Plan, implement, and evaluate nursing care related to select diagnoses/patient problems involving alterations in and related to mobility.

safe patient handling and mobility (SPHM)
spasticity
strength and endurance exercises
stretching exercise

tonus

This chapter describes the physiology of movement and factors affecting body alignment and mobility. The effects of immobility on body systems are discussed along with related nursing interventions. A guide for assessing body alignment and mobility states is included, with pertinent interview questions and physical assessment techniques. Analysis of patient mobility data may lead to the identification of issues related to impaired physical mobility or activity intolerance or the effects of mobility problems on other areas of human functioning. Examples of diagnoses/patient problems are included, expected outcomes are identified, and specific nursing strategies are presented. Assessment criteria, screening for patient handling decisions, and proper use of patient handling equipment are discussed. A section on exercise differentiates the types of exercise, explores the role of exercise in disease prevention and health promotion, notes risks related to exercise, and assists in the design of individualized exercise programs. The concluding Concept Map and Nursing Care Plan illustrate how the nurse uses knowledge of mobility and safe patient handling techniques along with specific nursing interventions to promote fitness and address mobility problems. The accompanying Reflective Practice box highlights important considerations to keep in mind when caring for patients with alterations in mobility and activity deficits.

PHYSIOLOGY OF MOVEMENT AND ALIGNMENT

Purposeful, coordinated movement of the body and maintenance of alignment require the integrated functioning of the musculoskeletal and nervous systems. The following sections review concepts related to movement and alignment.

Skeletal System

The framework of bones, the joints between them, and cartilage that protects our organs and allows us to move is called the skeletal system. Functions of this system include:

- Supporting the soft tissues of the body (maintains body form and posture)
- Protecting crucial components of the body (brain, lung, heart, spinal cord)
- Furnishing surfaces for the attachments of muscles, tendons, and ligaments, which, in turn, pull on the individual bones and produce movement
- Providing storage areas for minerals (such as calcium) and fat
- Producing blood cells (hematopoiesis)

The 206 bones in the human body are classified by their shape. Long bones, found in the upper and lower extremities (e.g., humerus and femur), contribute to height and length. Short bones, located in the wrist and ankle, contribute to movement. Flat bones are relatively thin (e.g., ribs and several of the skull bones) and contribute to shape (structural contour). Irregular bones are all those bones not included in the preceding classifications (e.g., bones of the spinal column and jaw).

Bones are too rigid to bend without damage. Therefore, all movements that change the positions of the bony parts of the body occur at joints. The terms *articulation* and *joint* refer to the area where a bone meets another bone. Joints are classified according to the amount of movement they permit and on the basis of the material between the adjoining bones. Types of joints are outlined in Table 34-1 (on page 1242). Diarthroses or synovial joints, joints in which there is a potential space containing lubricating synovial fluid between the articulating bones, are freely moving joints. Freely movable joints are discussed here in relation to the topic of activity.

Several types of freely movable joints are found in the body. These include:

- *Ball-and-socket joint:* The rounded head of one bone fits into a cuplike cavity in the other; flexion–extension, abduction–adduction, and rotation can occur (e.g., shoulder and hip joints).

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO TECHNICAL SKILLS

Last year during my medical-surgical clinical experience, I was taking care of Maggie Wyatt, a female patient in her 30s, with an external fixation device on her right leg. The patient had broken her tibia and had undergone three surgeries to try to correct the fracture. Maggie's current admission was for the treatment of an infection caused by the external device in place to treat the fracture. I was assigned to care for her on the day that she was being discharged. Throughout the day, I formed a close bond with her, and the nurse asked me to bring Maggie to her car when she was ready to leave. I was a little apprehensive about being able to help her into the car with the external fixator in place because she could not bend her leg at all. I had a couple of choices—I could take her down to the car myself and hope that there wouldn't be any problem helping her get into the car, or I could tell the nurse I didn't feel comfortable bringing the patient to the car because I didn't have any experience transferring patients with a device such as this one.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

However, I really wanted to bring this patient down and see her through the final stage of discharge.

Thinking Outside the Box: Possible Courses of Action

- Take the patient down to the car by myself and do the best I can to help transfer her to the car.
- Explain to the nurse that I don't feel that I have the skills to bring this patient down on my own and ask her to do it.
- Explain to the nurse that I would really like to bring the patient down to the car but that I do not feel that I have the experience to do it on my own; ask her to assist me.
- Ask the nurse about what the best way to transfer the patient to the car is before taking the patient to the car.

Evaluating a Good Outcome: How Do I Define Success?

- Patient receives the highest quality of care and has the least amount of pain possible during the transfer.
- I learn from the experience and gain skills and knowledge for the future.
- Patient is at least not harmed and is possibly benefitted by my action.

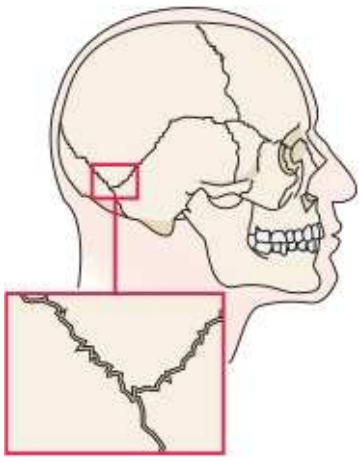
Personal Learning: Here's to the Future!

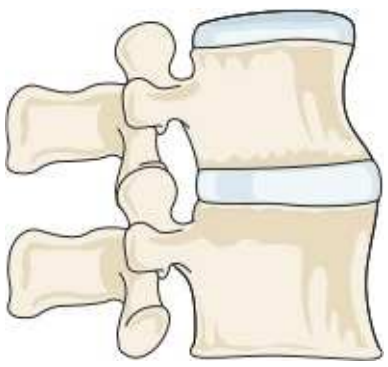
Unfortunately, in this case I did not make the right decision. I convinced myself that it could not be that difficult to transfer this very cooperative patient to her car with her mother's assistance. However, I definitely should have asked for assistance and screened the patient to identify appropriate safe patient handling and mobility equipment to use. The car was extremely small, and it was hard to get her to sit across the back seat while keeping her leg completely straight. The patient was experiencing a fair amount of pain from the device. So, every time we tried to get her into the car, she experienced more pain. Fortunately, a physical therapist came outside to help another patient and then also helped us. I realized that not only did I not have the skills to transfer her myself, but also that this was really a two-person job and required use of a transfer aid. The physical therapist showed me the best way to transfer this patient, and I learned a great deal from the experience. I was lucky that my patient was very understanding and accommodating in this situation. I gained some experience with transferring patients, but most importantly, I realized how important it is to trust your instincts and ask for help when you think you may need it—it's always better to be overprepared than underprepared.

Catherine Barrell, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? Do you agree with the criteria that the nursing student used to evaluate a successful outcome? Are there any other criteria that would be appropriate to use? Did the nursing student meet the criteria? Why or why not? What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve the quality and safety of care for patients like Ms. Wyatt?





Patient-Centered Care: What factors do you think might have influenced the nursing student's actions? Suppose that the patient was using crutches or a walker instead of having the fixation device in place. How might the nursing student's actions be different?

Teamwork and Collaboration/Quality Improvement: Imagine that the physical therapist did not arrive on the scene. What would have been the nursing student's next best action? What communication skills do you need to improve to ensure that you function as a member of the patient care team?

Safety/Evidence-Based Practice: What resources could the student have accessed to ensure the safe transfer of the patient? What evidence in nursing literature provides guidance for decision making regarding care of this patient? Can you think of other ways to respond to or approach the situation?

Table 34-1 Joints

TYPE	MOVEMENT	MATERIAL BETWEEN THE BONES	EXAMPLES

Fibrous 	Immovable (synarthrosis)	No joint cavity; fibrous connective tissue between bones	Sutures between bones of skull
Cartilaginous 	Slightly movable (amphiarthrosis)	No joint cavity; cartilage between bones	Pubic symphysis; joints between bodies of vertebrae
Synovial 	Freely movable (diarthrosis)	Joint cavity containing synovial fluid	Gliding, hinge, pivot, condyloid, saddle, ball-and-socket joints

Source: Reprinted with permission from Cohen, B. J., & Hull, K. L. (2019). Memmler's structure and function of the human body (12th ed.). Jones and Bartlett Learning.

- *Condyloid joint:* The oval head of one bone fits into a shallow cavity of another bone; flexion–extension and abduction–adduction can occur (e.g., wrist joint and joints connecting fingers to palm).
- *Gliding joint:* Flat surfaces of the bone slide over one another; flexion–extension and abduction–adduction can occur (e.g., carpal bones of wrist and tarsal bones of feet).
- *Hinge joint:* A spool-like (rounded) surface of one bone fits into a concave surface of another bone; only flexion–extension can occur (e.g., elbow, knee, ankle joints).
- *Pivot joint:* A ring-like structure that turns on a pivot; movement is limited to rotation (e.g., joints between the atlas and axis of the neck and between the proximal ends of the radius and the ulna at the wrist).
- *Saddle joint:* Bone surfaces are convex on one side and concave on the other; movements include flexion–extension, adduction–abduction, circumduction, and opposition (e.g., joint between the trapezium and metacarpal of the thumb).

Movements possible at diarthrodial joints include abduction, adduction, flexion, extension, and rotation. Special movements of the forearm, ankle, and clavicle include supination, pronation, inversion, and eversion. The thumb is the only joint that can perform opposition. These movements are defined in Table 34-2.

The strength and flexibility of the skeletal system also depend on ligaments, tendons, and cartilage. Ligaments are tough, fibrous bands of connective tissue that bind joints together and connect bones and cartilage. Tendons are strong, flexible, inelastic fibrous bands and flattened sheets of connective tissue that attach muscle to bone. Cartilage is hard, nonvascular connective tissue found in the joints as well as in the nose, ear, thorax, trachea, and larynx. Cartilage in joints functions as a shock absorber and provides a smooth surface that reduces friction between the moving parts of the joint. Fat may also provide padding at joints.

Muscular System

The muscular system is composed of three types of muscles: (1) skeletal, (2) cardiac, and (3) smooth or visceral muscles. Muscle tissue produces movement by contraction of its cells. Skeletal muscle works with tendons and bones to move the body. Cardiac muscle forms the bulk of the heart and produces the contractions that create the heartbeat. Smooth muscle forms the walls of the hollow organs (such as the stomach and intestines) and is in the walls of blood vessels and other hollow tubes (such as ureters) that connect internal organs. Skeletal muscle is discussed here in relation

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

to the topic of activity.

Table 34-2 Terms Commonly Used to Describe Body Positions and Movements

TERM	DEFINITION AND EXAMPLE
Abduction	Lateral movement of a body part away from the midline of the body. *Example:* A person's arm is abducted when it is moved away from the body.
Adduction	Lateral movement of a body part toward the midline of the body. *Example:* A person's arm is adducted when it is moved from an outstretched position to a position alongside the body.
Circumduction	Turning in a circular motion; combines abduction, adduction, extension, and flexion. *Example:* Circling the arm at the shoulder, as in bowling or a serve in tennis.
Flexion	The state of being bent. *Example:* A person's cervical spine is flexed when the head is bent forward, chin to chest.
Extension	The state of being in a straight line. *Example:* A person's cervical spine is extended when the head is held straight on the spinal column.
Hyperextension	The state of exaggerated extension. It often results in an angle greater than 180 degrees. *Example:* A person's cervical spine is hyperextended when looking overhead, toward the ceiling.
Dorsiflexion	Backward bending of the hand or foot. *Example:* A person's foot is in dorsiflexion when the toes are brought up as though to point them at the knee.
Plantar flexion	Flexion of the foot. *Example:* A person's foot is in plantar flexion in the footdrop position.
Rotation	Turning on an axis; the turning of a body part on the axis provided by its joint. *Example:* A thumb is rotated when it is moved to make a circle.
Internal rotation	A body part turning on its axis toward the midline of the body. *Example:* A leg is rotated internally when it turns inward at the hip and the toes point toward the midline of the body.
External rotation	A body part turning on its axis away from the midline of the body. *Example:* A leg is rotated externally when it turns outward at the hip and the toes point away from the midline of the body.
Special Movements	
Pronation	The assumption of the prone position. *Example:* A person is in the prone position when lying on the abdomen; a person's palm is prone when the forearm is turned so that the palm faces downward.
Supination	The assumption of the supine position. *Example:* A person is in the supine position when lying on the back; a person's palm is supine when the forearm is turned so that the palm faces upward.
Inversion	Movement of the sole of the foot inward (occurs at the ankle)
Eversion	Movement of the sole of the foot outward (occurs at the ankle)
Opposition	Rotation of the thumb around its long access (movement of the thumb across the palm to touch each fingertip of the same hand).

The skeletal muscle system includes the skeletal muscle tissue and connective tissue that comprise individual muscle organs, such as the biceps. Bones and joints provide form to the body and serve as the levers and fulcrums that make body movement possible. Movement results from a skeletal muscle contracting and exerting force on a tendon, which, in

turn, pulls on a bone. Muscles have two differing points of attachment: (1) the attachment of a muscle to the more stationary bone is called the point of origin, and (2) the attachment to the more movable bone is the point of insertion. Between these two points is the fleshy "belly" of the muscle. The excitability, contractility, extensibility, and elasticity of muscles enable them to perform four important functions for the body through contraction:

- *Motion:* Skeletal muscle contractions pull on tendons and move the bones, creating movements as simple as extending the arm to as highly coordinated as swimming or skiing.
- *Maintenance of posture:* Skeletal muscle contractions hold the body in stationary positions.
- *Support:* Skeletal muscles support soft tissues in the abdominal wall and floor of the pelvic cavity.
- *Heat production:* Skeletal muscle contractions produce heat and help maintain body temperature.

Figure 34-1 (on page 1244) illustrates the relationship of skeletal muscles to bones and the use of bones as levers and of joints as fulcrums to produce body movement.

Nervous System

The skeletal and muscular systems cannot produce purposeful movement without a functioning nervous system. Nerve impulses stimulate muscles to contract. More specifically:

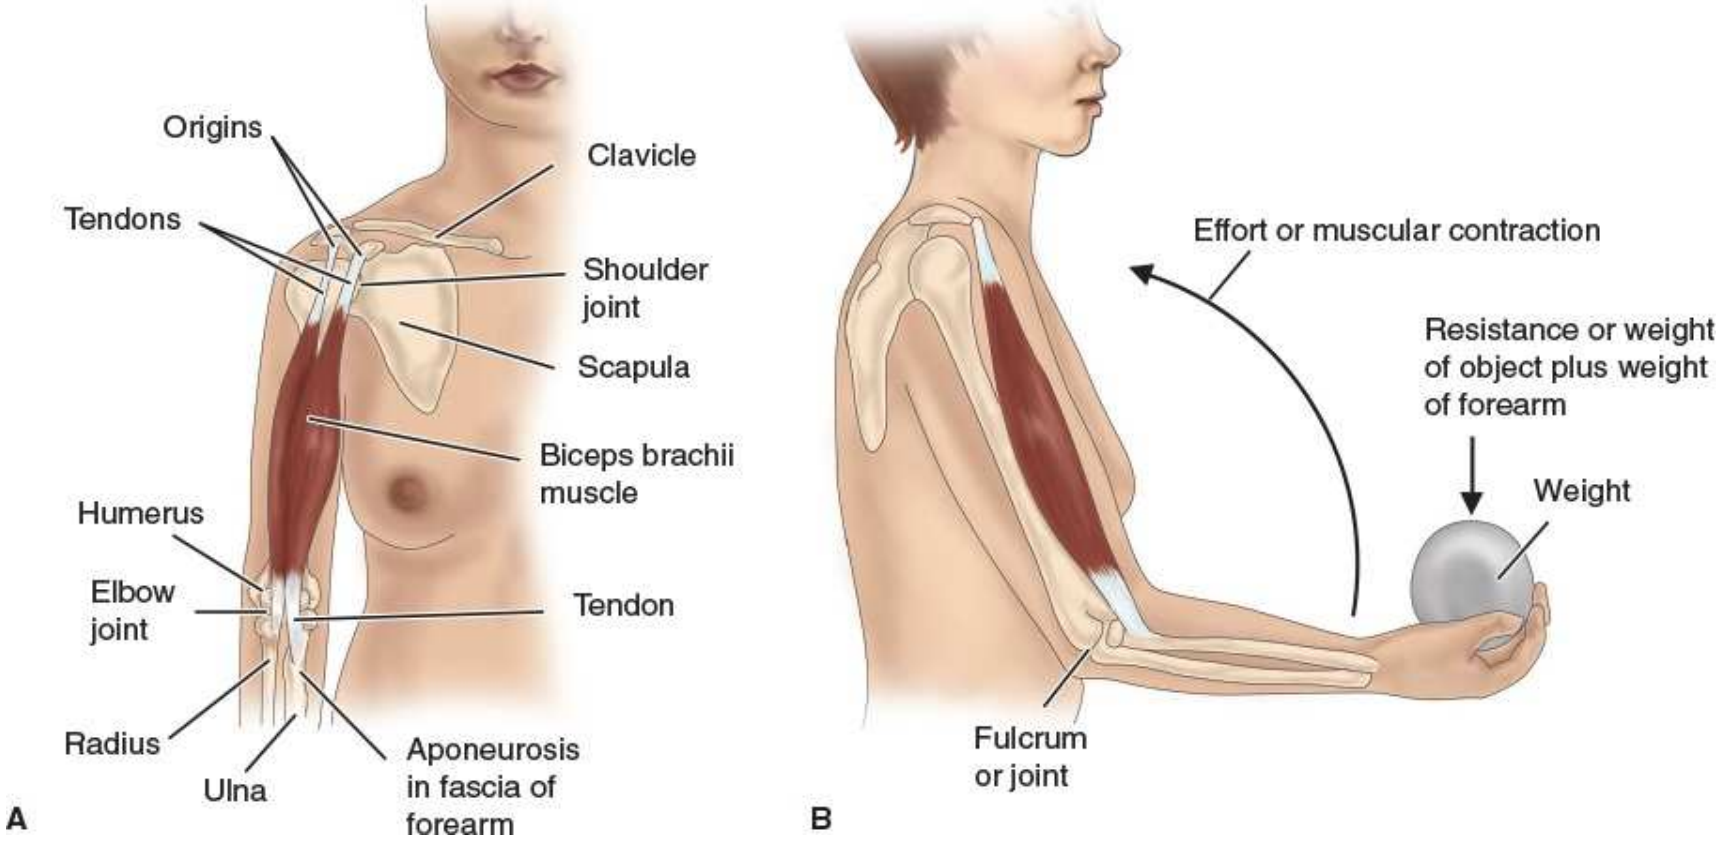


FIGURE 34-1. Relationship of skeletal muscles to bones. **A.** Skeletal muscles produce movements by pulling on bones. **B.** Bones serve as levers, and joints act as fulcrums for the levers. The lever and fulcrum principle is illustrated by the movement of the forearm lifting a weight.

- Nerve cells called neurons conduct impulses from one part of the body to another.
- The afferent neurons convey information from receptors in the periphery of the body to the central nervous system (CNS; e.g., light pressure on nose).
- This information is processed by the CNS, leading to a response (e.g., "There is a fly on my nose. I want to brush it off.").
- The efferent neurons convey the response from the CNS to skeletal muscles by way of the somatic nervous system (e.g., muscles in the arm, wrist, and hand contract, and the fingers brush the fly from the nose).

Normal Movement and Alignment

The following concepts are an important part of normal movement and musculoskeletal functioning and contribute to a person's overall well-being.

Body Alignment or Posture

Good posture, or proper body alignment, is the alignment of body parts that permits optimal musculoskeletal balance and operation and promotes healthy physiologic functioning. A person in correct alignment is experiencing no undue strain on the joints, muscles, tendons, or ligaments while balance is maintained.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Consider **Maggie Wyatt**, the woman being discharged with an external fixation device in place. Although the device is heavy and awkward and requires her to keep her right leg extended, body alignment is crucial for Maggie to prevent undue strain on other parts of her body.

The criteria for correct alignment in the standing, sitting, and reclining positions are described in the Assessing section on page 1257.

Balance

A body in correct alignment is balanced. An object is balanced when its center of gravity is close to its base of support, the line of gravity goes through the base of support, and the object has a wide base of support. The center of gravity of an object is the point at which its mass is centered. When the human is standing, the center of gravity is located in the center of the pelvis about midway between the umbilicus and the symphysis pubis. The line of gravity is a vertical line that passes through the center of gravity. The base of support is the foundation that provides for an object's stability. The wider the base of support and the lower the center of gravity, the greater the stability of the object will be. Figure 34-2 illustrates the effect of the base of support and gravity on body balance.

Body balance increases when people spread the feet farther apart and flex the hips and knees. This broadens the base of support and lowers the center of gravity. These two simple maneuvers are important interventions that can decrease the musculoskeletal strain that occurs with excessive stretching or overexertion of a muscle or muscle–tendon unit. Musculoskeletal strain most commonly affects the lower back and cervical spine region. Trauma to the musculoskeletal system is discussed on page 1249.

Coordinated Body Movement

Coordinated body movement is the ability of muscles to work together for purposeful movement. Using major and stronger muscle groups, rather than weaker ones, and taking advantage of the body's natural levers and fulcrums facilitates the actions of lifting, carrying, pushing, pulling, and moving objects. Major muscle groups include the flexors, extensors, and abductors of the thighs; flexors and extensors of the knees; and flexors and extensors of the upper and lower arms. For example, use of the arm bones as levers and the elbows as fulcrums facilitates lifting a weight against resistance, the force of gravity—the lever and fulcrum principle (see Fig. 34-1).

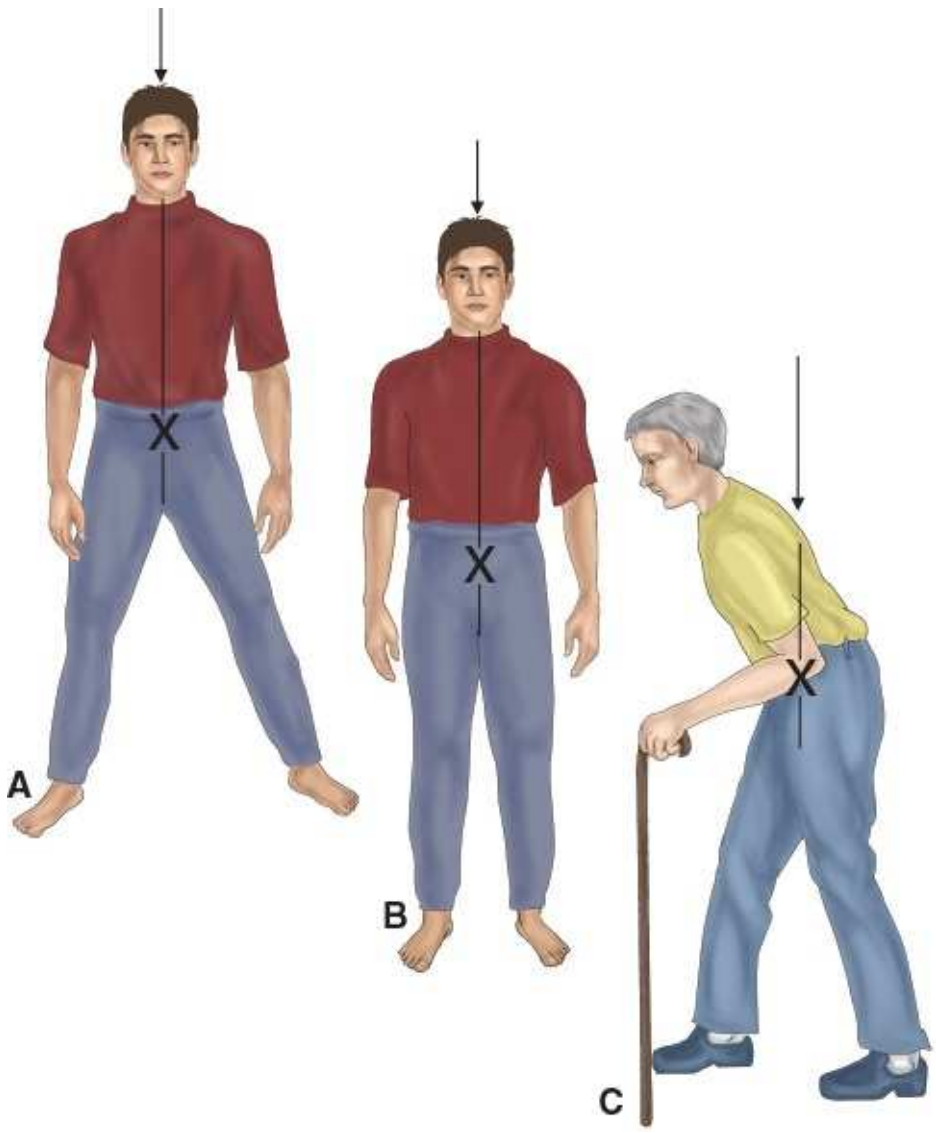

FIGURE 34-2. The effect of the base of support and gravity on balance is shown. **A.** The line of gravity passes through the wide base of support. This person is the most stable of the three. **B.** The line of gravity also passes through the base of support, although the base is narrower. This person is less stable than the person in **A. C.** The line of gravity does not pass through the base of support. This person is unstable.

Postural Reflexes

Postural reflexes are the group of reflexes (automatic movements) that maintain body position and equilibrium, whether at rest or during movement. Integrated functioning of the musculoskeletal and nervous systems is essential for body alignment and balance. Postural tonus, the sustained contraction of select skeletal muscles that keeps the human body in an upright position against the force of gravity, depends on the functioning of several postural reflexes:

- The sensory organs in the inner ear provide a sense of position, orientation, and movement. Body movement (e.g., changes in head position) stimulates the sensory organs, which then transmit these impulses to the cerebellum.
- Joint movements stimulating special nerve endings in muscles, tendons, and fascia inform the brain of the location of a limb or body part.
- Visual impressions contribute to posture by alerting the person to spatial relationships with the environment (nearness of ceilings, walls, furniture, condition of floor, etc.).
- When extensor muscles are stretched beyond a certain point (e.g., when knees buckle under), their stimulation causes a reflex contraction that aids a person to reestablish erect posture (e.g., straighten the knee).

Safe Patient Handling and Mobility

Ergonomics is the practice of designing equipment and work tasks to conform to the capability of the worker and provides a means for adjusting the work environment and work practices to prevent injuries (OSHA, n.d.b). The use of proper body positions and avoidance of awkward postures provide protection from the stress of movement and activity (OSHA, n.d.b). Ergonomics includes proper body movement in daily activities, the prevention and correction of problems associated with posture, and the enhancement of coordination and endurance. It is important to use the principles of ergonomics during activity and during rest periods to prevent injury and to prevent sore muscles and joints. Many activities in which the nurse engages to move objects, from as simple an activity as moving a chair, repositioning the medication cart, or reaching to silence a monitor alarm, require understanding and using these principles. Nurses who consciously develop good habits when moving objects can demonstrate to others proper ways of using the musculoskeletal system. The application of ergonomics is discussed in the Implementing section of the Nursing Process on pages 1260–1262.

Ergonomics applied to activities associated with direct patient care is known as **safe patient handling and mobility (SPHM).** It is very important to incorporate safe patient handling and mobility interventions into nursing practice and patient care. Frequently, it is necessary to move patients who are weak or unable to move on their own. However, manual lifting, transferring, and repositioning of patients are high-risk activities for nurses and patients. Even routine repetitive care activities, such as changing bed linens and bathing patients, have the potential to cause back injury.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Self-Care Alert

Nurses are at high risk for musculoskeletal injuries from moving patients. Implement patient handling and mobility equipment as a best practice. Be familiar with the safe patient handling equipment available in your facility; understanding how to choose and use appropriate devices is a priority for self-care and safe patient care.

Injuries and musculoskeletal disorders are often caused by manually lifting patients, and nurses are at high risk every day (American Nurses Association [ANA], n.d.a). Patient handling injuries represent more than 20% of injuries to nurses (Hodgson et al., 2013). Nurses report musculoskeletal pain caused or exacerbated by their work and chronic back pain (Fragala et al., 2016). Of nurses in the United States, as many as 20% leave direct patient care positions because of risks associated with the work (OSHA, n.d.a). Many nurses say they have had episodes of occupation-related back problems and accept back pain as a routine consequence of the job—but this need not be. Variables that can lead to patient handling injuries include the following:

- Uncoordinated lifts
- High exertion (force required to life, move or handle patient) while in an awkward posture
- Assuming awkward and static postures
- Manual lifting and transferring of patients without assistive devices
- Lifting when fatigued
- Repetitive movements such as lifting, transferring, and repositioning patients
- Standing for long periods of time
- Transferring patients from beds to stretchers and chairs, wheelchairs, or operating tables; repositioning patients in bed
- Repetitive tasks
- Transferring/repositioning patients who have cognitive impairments, who are dependent/obese/overweight, or patients who are unable or unwilling to actively participate and promote their own movement (Fragala et al., 2016).

A more effective approach to safe patient transfers includes patient assessment criteria; screening and algorithms for patient handling and mobility decisions; specialized patient handling equipment used properly and operated using proper ergonomics; and the use of lift teams. The proper use of assistive devices to lift, move, reposition, and transport patients is key to SPHM (Fragala et al., 2016). In addition, the use of assistive patient handling equipment contributes to patient comfort and protects patient dignity, while increasing safety.

Research supports the consistent use of standardized protocols and assistive devices as an effective approach to decrease the risk of injury for health care workers (Nelson, 2015; Nelson et al., 2009). The National Institute for Occupational Safety and Health (NIOSH) (2013), Joint Commission and the Occupational Safety & Health Administration (OSHA) recommend a no-lift policy in conjunction with technology, assistive devices, education, and a culture of safety for all health care facilities (Fragala et al., 2016; OSHA and Joint Commission Resources Alliance, 2017). Implementing safe patient handling and mobility programs improves the quality of patient care and reduces the risk of harm for patients and health care workers (Nelson, 2015; OSHA and Joint Commission Resources Alliance, 2017).

Preventive measures should focus on careful assessment of the patient care environment so that patients can be moved safely and effectively. The use of a back-belt does not prevent back injury. In some institutions, specially trained staff members who function as “back injury resource nurses” are responsible for assisting nurses to assess patients. Other institutions have created “lift teams” or “patient lift teams” as part of their institution’s safe patient handling policy. Lift teams are groups of specially trained staff that provide safe patient transfers (Graulich et al., 2018; Lee et al., 2015; OSHA, n.d.b). The application of safe patient handling and mobility is discussed in detail in the Implementation section of the Nursing Process on pages 1261–1262.

Orthopedics

Orthopedics refers to the correction or prevention of disorders of body structures used in locomotion. Nurses recognize that basic orthopedic principles apply in all areas of nursing, not just to patients with bone fractures or other pathologic skeletal changes. For example, a person who has a sedentary occupation and engages in little physical activity may have poorly developed muscles. A patient who is on complete bed rest is in danger of losing muscle tonus. **Tonus** is the term used to describe the state of slight contraction—the usual state of skeletal muscles. If bed rest is prolonged, the patient is in danger of developing **contractures** (permanent contraction of a muscle) unless exercise, joint motion, and good posture are maintained. Positioning and movement, or lack thereof, also influence the functioning of various internal body processes.

FACTORS AFFECTING MOVEMENT AND ALIGNMENT

Numerous factors, including growth and development, physical health, mental health, lifestyle variables, attitude and

values, fatigue and stress, and external factors such as weather influence a person's posture, movement, and daily activity level.

Developmental Considerations

A person's age and degree of neuromuscular development markedly influence body proportions, posture, body mass, movements, and reflexes. To promote neuromuscular development in patients of all ages and to facilitate each patient's use of the body to perform self-care activities, nurses need to be familiar with developmental variations in body proportions and neuromuscular development. These variations are presented in Table 34-3 along with related nursing assessment priorities and nursing interventions.

Recall **Kelsi Lester**, the 10-year-old girl in a coma. Typically, children of this age are highly active and mobile. However, Kelsi is immobile and confined to bed due to her accident. The nurse would obtain a history of Kelsi's activity level before the accident to determine her neuromuscular development. The nurse would then use this information to develop an age-appropriate plan of care to maximize Kelsi's level of function.

Physical Health

Problems in the musculoskeletal or nervous systems can have a negative influence on body alignment and movement. Similarly, illness or trauma involving other body systems may interfere with movement because of either the underlying pathology or the treatment regimen. Nurses must be sensitive to how both acute and chronic health problems affect a patient's general appearance (posture, body proportions, and movements), their ability to move purposefully to perform **activities of daily living (ADLs)** and **instrumental activities of daily living (IADLs)** or self-care activities, and maintain their quality of life (functional health) (Jarvis & Eckhardt, 2020; Jensen, 2019). Eating, bathing, dressing, and toileting are examples of ADLs. Housekeeping, meal preparation, management of finances, and transportation are examples of IADLs. When assessing a patient's response to a mobility deficit, work to:

Table 34-3 Activity Variations Based on Developmental Level: Assessment Priorities and Nursing Interventions

DEVELOPMENTAL LEVEL	ASSESSMENT PRIORITIES	NURSING INTERVENTIONS
Infant • Periods of activity and alertness alternate with quiet periods and sleep. • At 3 months: May raise chest and head when prone. • By 5 months: Head control usually achieved.	Assess the following key developmental milestones at these ages: **3–6 months** • Ability to sit • Head control **6–9 months** • Sits steadily • Rolls over • Creeps on all fours • Pulls to a standing position • Has improved hand–eye coordination	• Encourage parents to examine their baby. • Respond to concerns that parents have about minor variations in newborn's appearance or behavior. • Emphasize that individual variation in activity patterns and neuromuscular development should be expected. • Account for any prematurity when discussing normal developmental progression of preterm infants.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	9–12 months • Progresses toward unassisted walking • Is able to pick up small objects	
Toddler • Gross and fine motor development continues rapidly. • By 15 months: Most can walk unassisted. • At 18 months: Most can run. • At 2 years: Most can jump. • At 3 years: Most can stack blocks, work simple puzzles, and dress themselves.	• Assess progress in walking, running, and jumping. • Assess small-muscle coordination (e.g., ability to dress themselves, wash hands, brush teeth). • Distinguish slow developers who fall within normal range from those with developmental lags.	• Help parents to learn and accept their child's uniqueness. • Teach parents the importance of providing a safe environment. • Enthusiastically reinforce and praise toddler's mastery of new skills. • Set limits so that toddler does not overextend self in drive for mastery of skills.
Child • Greater gross and fine motor control. • By age 4: Negotiate stairs, walk backward, and hop on one foot. • By age 5: Skip, jump rope, and jump off heights of several steps. • Able to manipulate writing materials.	• Use developmental charts to assess gross and fine motor development. • Determine activity level and types of play that involve physical exertion.	• Teach parents that attitudes about the body and exercise are developed during this period. • Counsel as appropriate. • Assess safety issues and reinforce safety teaching at each stage.
Adolescent • Size increases: There is a growth spurt. • Secondary sex characteristics appear. • If physically fit: Can be a time of boundless energy and great athletic performance. • If inactive: May begin a lifelong pattern of unhealthy behavior.	• Determine activity level and type of regular exercise. • Evaluate safety of recreational choices. • Screen for scoliosis (lateral curvature of the spine). • Examine muscle mass, tone, and strength and joint mobility.	• Encourage physical activity, regular exercise, and limitation of sedentary hobbies. • Lifestyle counseling regarding the importance of exercise and fitness is critical. • Encourage to exercise regularly if necessary. • Caution about gauging physical limits and not "pushing too hard."
Adult • Stands and sits erect and is capable of balanced and coordinated purposeful movement. • During pregnancy: center of gravity shifts because of developing fetus. • Activity levels vary greatly.	• Assess balance between activity and rest in person's lifestyle. • Note any lifestyle factors or illnesses that interfere with mobility or ability to carry out activities of daily living.	• Fitness counseling is important. • Clarify misconceptions about exercise. • Design and monitor safe exercise programs. • Those with mobility alterations may require special care.
Older Adult • Increased convexity in the thoracic spine (kyphosis) from disk shrinkage and decreased height • Loss of muscle tone • Subcutaneous fat loss • Arthritic joint changes may be	• Assess general ease of movement and gait. • Assess alignment. • Check joints and their function. • Assess muscle mass, tone, and strength.	• Teach and counsel about: • Importance of regular exercise • Need for high protein, calcium, and vitamin D–enriched diet • Pacing activities • Using assistive devices safely

present	when needed • Safety-proof home to reduce falls

- Encourage attempts at behaviors that promote self-care activities despite limitations (e.g., offer supportive suggestions to patients who attempt to feed themselves despite having hemiparesis).
- Reinforce behaviors that promote healthy functioning (e.g., congratulate a patient who manages transfers well despite left-sided weakness or paralysis).
- Correct behaviors that compound the mobility deficit over time (e.g., teach adaptive strategies that can be shared with other patients and families to a patient with arthritis who severely restricts movement because of joint stiffness and tenderness; or teach energy conservation measures to patients with emphysema who have greatly decreased activity tolerance).

Additional information related to activities of daily living, as well as functional health, is discussed in the Physical Assessment discussion later in this chapter and in Chapter 27.

Muscular, Skeletal, or Nervous System Problems

Problems with the musculoskeletal or nervous systems may involve one or more of the following health issues.

CONGENITAL OR ACQUIRED POSTURAL ABNORMALITIES

Postural abnormalities that affect appearance and mobility may be congenital in origin or acquired. Examples of patients experiencing one of these abnormalities include a newborn with developmental hip dysplasia, torticollis (lateral deviation of the neck) or a clubfoot; a teenager with lordosis (exaggerated anterior convex curvature of the spine) or scoliosis (lateral curvature of the spine); and an older adult with kyphosis (increased convexity in the curvature of the thoracic spine). Nursing responsibilities may include the following:

- Early detection of and referral for these problems
- Exploration and selection of patient education, counseling, and support as treatment options
- Careful attention to positioning, transfers, and exercise
- Education of the patient and family/caregivers regarding safe self-care activities

PROBLEMS WITH BONE FORMATION OR MUSCLE DEVELOPMENT

Problems with bone formation may include any of the following:

- Congenital problems, such as achondroplasia, in which premature bone ossification (bone tissue formation) leads to dwarfism or osteogenesis imperfecta, which is characterized by excessively brittle bones and multiple fractures both at birth and later in life
- Nutrition-related problems, such as vitamin D deficiency, which results in deformities of the growing skeleton (rickets)
- Disease-related problems, such as Paget's disease, in which excessive bone destruction and abnormal regeneration result in skeletal pain, deformities, and pathologic fractures
- Age-related problems, such as osteoporosis, in which bone destruction exceeds bone formation and in which the resultant thin, porous bones fracture easily

Problems with muscle development may be genetic in origin, a disease-related problem, or an age-related problem. The muscular dystrophies are a group of genetically transmitted disorders that share a common progressive degeneration and weakness of skeletal muscles. They vary in terms of the muscle groups involved and their clinical course. Myasthenia gravis is a weakness of the skeletal muscles caused by an abnormality at the neuromuscular junction that prevents muscle fibers from contracting. Myotonic muscular dystrophy involves prolonged muscle spasms or stiffening after use. Duchenne muscular dystrophy involves a muscle decrease in size, as well as weakening of muscles over time.

Nursing responsibilities for patients with problems of bone formation and muscle development and functioning include the following:

- Careful collaboration with the health care team to determine the motor capacities of the person
- Patient and family/caregiver education aimed at developing optimal mobility
- The ability to position, transfer, and exercise the patient safely, with attention to patient comfort

PROBLEMS AFFECTING JOINT MOBILITY

Inflammation, degeneration, and trauma can all interfere with joint mobility. The term *arthritis* describes more than 100 different diseases that affect areas in or around joints. Arthritis is characterized by inflammation, pain, damage to joint, stiffness and/or decreased range of motion (Arthritis Foundation, n.d.b; Centers for Disease Control and Prevention [CDC], 2020a). The most common type is osteoarthritis, also termed *degenerative joint disease*. Osteoarthritis is a noninflammatory, progressive disorder of movable joints, particularly weight-bearing joints, characterized by the deterioration of articular cartilage and pain with motion (Arthritis Foundation, n.d.a). Once the articular cartilage is damaged, bony deposits (bone spurs) may form in the joints, causing more pain with movement of the joint.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Remember **Mrs. Nguyen**, the older woman concerned about caring for her husband at home. The nurse would need to consider the impact of possible age-related issues as contributing to Mrs. Nguyen's current problems with bone and joint pain. Due to her older adult status, the likelihood of osteoporosis and degenerative joint disease is high. Therefore, teaching to minimize stress on the joints when assisting with her husband's care would be important in preventing possible bone and joint injuries and reducing pain.

Trauma to a joint may result in a sprain or a dislocation. A sprain occurs with the wrenching or twisting of a joint, resulting in a partial tear or rupture to its attachments. A dislocation is characterized by the displacement of a bone from a joint with tearing of ligaments, tendons, and capsules. Any condition restricting joint mobility has potentially crippling effects.

Nurses caring for patients with joint problems work collaboratively with physicians, other advanced practice professionals, physical therapists, and other health care professionals to maintain joint mobility. Patient education is directed to the patient's mastery of an exercise and care program, which fosters tissue repair and maximal independence in ADLs.

Think back to **Maggie Wyatt**, the woman being discharged after treatment for a fractured tibia. The nurse would need to work closely with other members of Maggie's health care team to ensure that joint mobility is maintained, even with the device in place. The discharge teaching plan would include measures to maintain function of the right leg while the external fixation device immobilizes the fractured area.

TRAUMA TO THE MUSCULOSKELETAL SYSTEM

Injury to the musculoskeletal system can result in fractures and soft tissue injuries. A fracture, a break in the continuity of a bone or cartilage, may result from a traumatic injury or some underlying disease process. Healing requires realignment of the bone fragment, immobilization, and restoration of the bone's function. Soft tissue injuries include sprains, strains, and dislocations (sprains and dislocations are discussed in the previous section, Problems Affecting Joint Mobility). A strain, the least serious of these injuries, is a stretching of a muscle. Nurses need to be knowledgeable in first aid measures for musculoskeletal trauma as well as in acute and rehabilitative care.

PROBLEMS AFFECTING THE CENTRAL NERVOUS SYSTEM

A problem in any of the parts of the brain or spinal cord involved with skeletal muscle control can affect mobility. The cerebral motor cortex assumes the major role of controlling precise, discrete movements. A cerebrovascular accident (stroke) or head trauma may damage the motor cortex and produce temporary or permanent voluntary motor impairment. Basal ganglia integrate semivoluntary movements such as walking, swimming, and laughing. In Parkinson's disease, there is progressive degeneration of the basal ganglia of the cerebrum, thus affecting walking and coordination. Unnecessary skeletal movements result in tremors and muscle rigidity, which interfere with voluntary movement. The cerebellum assists the motor cortex and basal ganglia by making body movements smooth and coordinated. In multiple sclerosis, the myelin sheaths of neurons in the central nervous system (CNS) deteriorate to hardened scars or plaques. Plaque formation in the cerebellum may produce lack of coordination, tremors, and/or weakness.

The pyramidal pathways of the nervous system convey voluntary motor impulses from the brain through the spinal cord by way of two major pathways: (1) the pyramidal pathway and (2) the extrapyramidal pathway. With trauma to the spinal cord, transection (severing) of these motor pathways results in complete bilateral loss of voluntary movement below the level of the trauma.

Nurses caring for patients with injury to the CNS need to be knowledgeable about the pathology and clinical course

of these diseases to provide appropriate patient education and counseling. Education and counseling are directed at addressing how the disease may progress and how it may affect the patient's functioning.

Recall **Kelsi Lester**, the 10-year-old in a coma after a skiing accident. Although Kelsi is unconscious, the nurse must communicate with her, making sure to explain everything that is happening to her and all that is being done. In addition, the nurse would need to communicate with Kelsi's family to ensure that they understand what is happening. For example, the nurse needs to explain the reasons for frequent turning, position changes, and exercises while Kelsi is unconscious.

Problems Involving Other Body Systems

The pathology of numerous other acute and chronic illnesses may also affect mobility. Chronic obstructive pulmonary disease and conditions such as ascites (accumulation of fluid in the peritoneal cavity) may alter posture. Any illnesses that interfere with oxygenation at the cellular level decrease the amount of oxygen available to the muscles for work and thus decrease activity tolerance. These illnesses include anemia, angina, cardiac arrhythmias, heart failure, and chronic obstructive pulmonary disease. Diseases characterized by a larger breakdown of protein than that which is manufactured, such as anorexia nervosa and certain cancers, lead to a negative nitrogen balance that results in muscle wasting and decreased physical energy for movement and work. Symptoms accompanying many illnesses, such as fatigue, muscle aches, and pain, may also lead to immobility. Bed rest is an important component of treatment for many diseases or trauma states, such as some surgeries and fractures. Although rest is essential for the healing process, immobility associated with bed rest may cause its own problems. Table 34-4 outlines a comparison of the effects of immobility and exercise on body systems. Nurses need to be vigilant in determining the effects of any injury or illness on mobility and in providing care to facilitate optimal mobility as early as possible.

Table 34-4 Comparison of Effects of Exercise and Immobility on Body Systems

BODY SYSTEM	EFFECTS OF EXERCISE	EFFECTS OF IMMOBILITY
Cardiovascular System	↑ Efficiency of heart	↑ Cardiac workload
	↓ Resting heart rate and blood pressure	↑ Risk for orthostatic hypotension
	↑ Blood flow and oxygenation of all body parts	↑ Risk for venous thrombosis
Respiratory System	↑ Depth of respiration	↓ Depth of respiration
	↑ Respiratory rate	↓ Rate of respiration
	↑ Gas exchange at alveolar level	Pooling of secretions
	↑ Rate of carbon dioxide excretion	Impaired gas exchange
Gastrointestinal System	↑ Appetite	Disturbance in appetite
	↑ Intestinal tone	Altered protein metabolism Altered digestion and utilization of nutrients ↓ Peristalsis
Urinary System	↑ Blood flow to kidneys	↑ Urinary stasis
	↑ Efficiency in maintaining fluid and acid–base balance	↑ Risk for renal calculi

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	↑ Efficiency in excreting body wastes	↓ Bladder muscle tone
Musculoskeletal System	↑ Muscle efficiency ↑ Coordination ↑ Efficiency of nerve impulse transmission	↓ Muscle size, tone, and strength ↓ Joint mobility, flexibility Bone demineralization ↓ Endurance, stability ↑ Risk for contracture formation
Metabolic System	↑ Efficiency of metabolic system ↑ Efficiency of body temperature regulation	↑ Risk for electrolyte imbalance Altered exchange of nutrients and gases
Integument	Improved tone, color, and turgor, resulting from improved circulation	↑ Risk for skin breakdown and formation of pressure injuries
Psychological Well-Being	Energy, vitality, general well-being Improved sleep Improved appearance Improved self-concept Positive health behaviors	↑ Sense of powerlessness ↓ Self-concept ↓ Social interaction ↓ Sensory stimulation Altered sleep–wake pattern ↑Risk for depression Risk for learned helplessness

Mental Health

A person's mental health influences body appearance and movement as much as the person's physical health. Body processes tend to slow down with depression, and there is a lack of visible energy and enthusiasm. Body posture also may be affected. For example, the person with depression often sits with head bowed and shoulders slumped, and may lack the energy to eat or even to use the toilet. Even facial movement may be decreased to the point at which the person's face registers no emotion (termed a flat affect). Conversely, people who are not depressed are more likely to have erect posture, animated facial features, and energy for routine activities.

Lifestyle

Whether a person chooses an active or sedentary lifestyle is dependent on many variables, including occupation, leisure activity preferences, and cultural influences. Many occupations are sedentary (e.g., computer technician). Therefore, people in sedentary occupations wishing to exercise regularly need to plan ahead for these leisure activities by preparing to exercise before or after work hours or during a lunch break. People may also participate in leisure activities that are sedentary in nature such as reading, debating, crafts, and watching television. In addition, a person's diet and smoking history are other lifestyle variables that influence mobility.

Culture may also play a role, encouraging or discouraging exercise. Identifying culturally acceptable physical activities is an important step in planning a program of physical activity. Physical activities that are congruent with overall lifestyle and cultural context and planned in the context of a patient-centered approach will be easier to incorporate into daily living (Andrews et al., 2020; Lee & Im, 2010). The nurse should include the patient and family members/caregivers to determine preferred activities to devise a plan for increasing activity level.

Attitude and Values

In some families, such as those who hike, swim, or play ball together, children learn early to value regular exercise. As these children mature, they often continue to value exercise and find new ways to incorporate regular exercise into their daily routine. On the other hand, children may be raised in families who are sedentary and in which watching sports is the closest anyone comes to exercise. Attitudes and values learned early may be internalized for a lifetime. Individual values also influence the exercise options people make. People who place a high value on physical attractiveness may be highly committed to regular exercise because it helps produce the body they want. Another person may exercise because of the desire for physical strength, relating strength with power. However, someone more disposed to intellectual pursuits may perceive body development as simply wasting time that could be better used to develop the mind. Sometimes, people view exercise as too much of a chore, and thus avoid it. It is important to offer suggestions for how to incorporate exercise into the person's daily routine, making exercise less of a chore.

Fatigue and Stress

Chronic stress may deplete body energy to the point that fatigue makes even the thought of exercise overwhelming. Ironically, regular exercise is energizing and can better equip a person to deal with daily stresses. Excessive exercise, however, may stress the body and lead to injury as well as to fatigue.

External Factors

Many external factors can influence activity and mobility. Among these, weather probably exerts the greatest influence over outside exercise. A brisk, clear day is invigorating and invites increased activity. However, high humidity, very hot and very cold temperatures, rain, and snow discourage outdoor exercise. Nurses need to consider appropriate forms of exercise and social determinants when developing exercise recommendations to patients (Physiopedia, n.d.). Sufficient financial resources for gym memberships, access to exercise equipment, safe outdoor parks and sports areas, the availability of malls for early morning walkers, support people, and occupational or insurance rewards for exercise can all encourage regular exercise. Discouraging factors include lack of free time, insufficient financial resources for equipment purchase or gym membership, air pollution, unsafe neighborhoods, and lack of support and reinforcement. For example, walking is a commonly prescribed exercise. However, walking may pose a threat to the person who only has access to walk in unsafe environments, such as high-crime areas.

EXERCISE

Active exertion of muscles involving the contraction and relaxation of muscle groups is termed exercise. Each of the many different types of exercise can produce different physiologic and psychological benefits.

Types of Exercise

Exercise can be divided into two major types. One is based on the type of *muscle contraction* occurring during the exercise. The second is based on the type of *body movement* occurring and the health benefits achieved.

Muscle Contraction

Exercise may be categorized according to the type of muscle contraction involved as being isotonic, isometric, or isokinetic (Fig. 34-3 on page 1252).

Isotonic exercise involves muscle shortening and active movement. Examples include carrying out ADLs, independently performing range-of-motion exercises, and swimming, walking, jogging, and bicycling. Potential benefits include increased muscle mass, tone, and strength; improved joint mobility; increased cardiac and respiratory function; increased circulation; and increased osteoblastic or bone-building activity. These benefits do not occur when the nurse or family member/caregiver performs passive exercises for a patient because the patient's muscles do not exert effort. Therefore, although still beneficial, the overall potential benefits are reduced.

Isometric exercise involves muscle contraction without shortening (i.e., there is no movement or only a minimum shortening of muscle fibers). Examples include contractions of the quadriceps and gluteal muscles, such as what occurs when holding a yoga pose. Potential benefits are increased muscle mass, tone, and strength; increased circulation to the exercised body part; and increased osteoblastic activity. Nurses should encourage both isotonic and isometric exercises for hospitalized patients with limited mobility.

Isokinetic exercise involves muscle contractions with resistance. The resistance is provided at a constant rate by an external device, which has a capacity for variable resistance. Examples include rehabilitative exercises for knee and elbow injuries and lifting weights. Using the device, the person takes the muscles and joint through a complete **range of motion** (the maximum degree of movement of which a joint is normally capable) without stopping, meeting resistance at every point. A continuous passive motion (CPM) device used postoperatively after joint surgery (e.g., total knee replacement) performs these same type exercises passively for the patient.

Consider **Maggie Wyatt**, the woman being discharged with an external fixation device in place. A specific exercise routine that includes isotonic and isometric exercises would most likely be prescribed for Maggie. Later in the course of Maggie's treatment, after her fracture has healed, isokinetic exercises may be included to strengthen her right leg.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

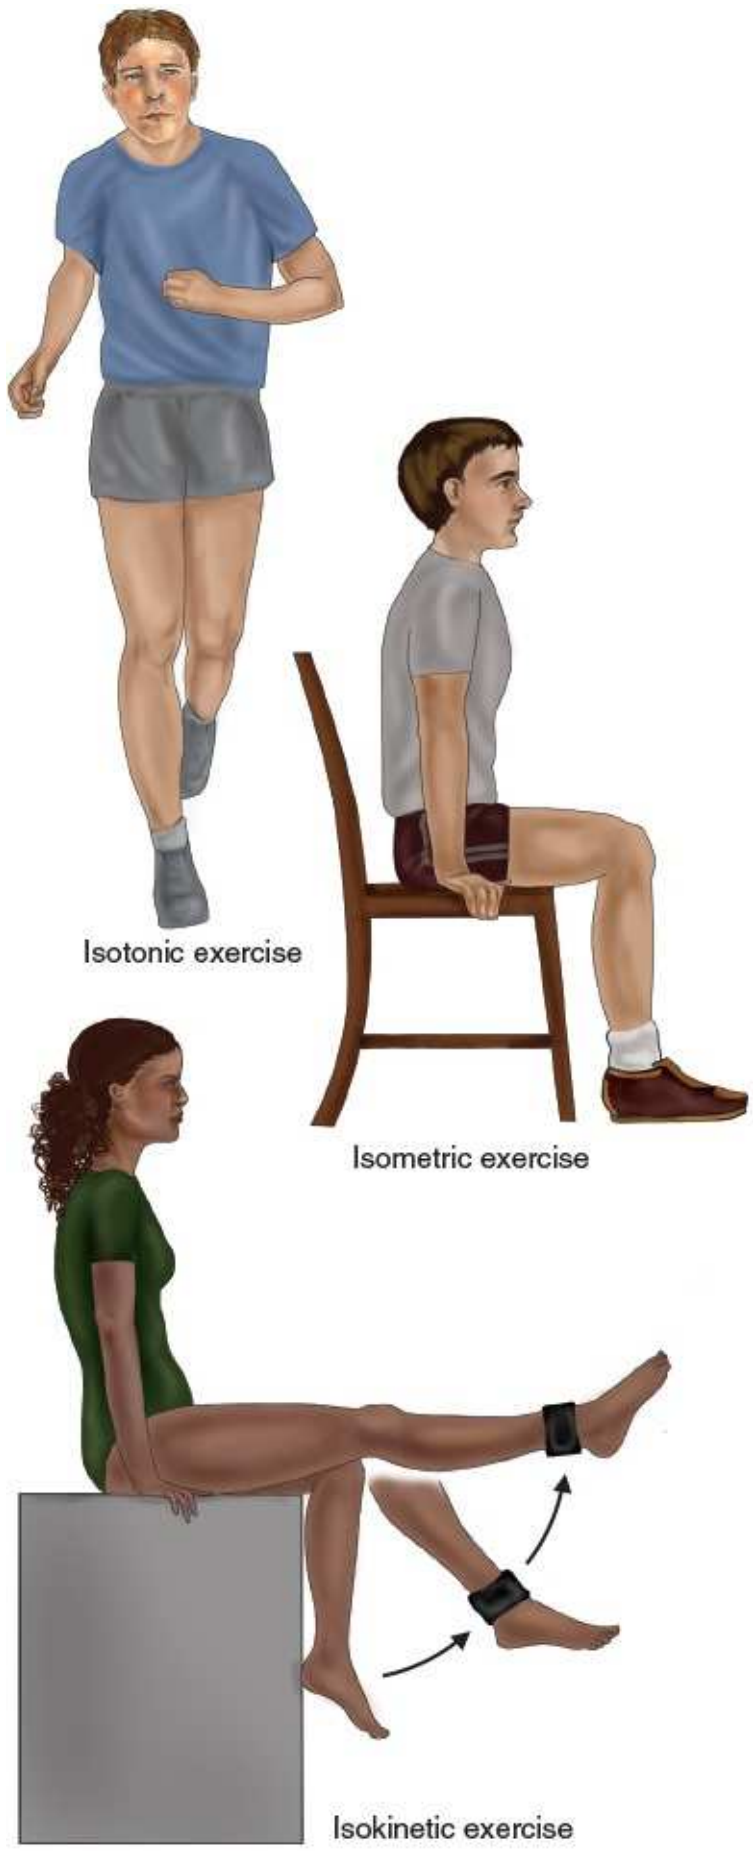

FIGURE 34-3. Three types of exercise. *Isotonic exercise* involves muscle shortening and active movement. *Isometric exercise* involves muscle contraction without shortening. *Isokinetic exercise* involves muscle contraction with resistance.

Body Movement

Exercise activities may also be categorized according to the type of body movement involved and the health benefits they produce. Types of exercise involving body movement include aerobic exercises, stretching exercises, strength and endurance exercises, and movement and ADLs.

Aerobic exercise refers to sustained (often rhythmic) muscle movements that increase blood flow, heart rate, and metabolic demand for oxygen over time, promoting cardiovascular conditioning. Examples of aerobic activities include swimming, walking, jogging, cross-country skiing, aerobic dancing, bicycling, jumping rope, and racquetball. Aerobic exercise may be further distinguished as having high or low impact. The number of injuries, such as shin splints, related to high-impact aerobic workouts led to the development of low-impact workouts that place less stress on the musculoskeletal system. Low-impact aerobic exercises include those activities in which at least one foot is on the ground at all times, like walking, rowing, or riding a stationary bicycle. High-impact exercises include activities that are more apt to jar the spine, like running, jumping, or kick-boxing.

Stretching exercise involves movements that allow muscles and joints to be stretched gently through their full range of motion, increasing flexibility. Specific warm-up and cool-down exercises, Hatha yoga, and some forms of dance are examples. Benefits include increased range-of-joint movements, improved circulation and posture, and relaxation.

Strength and endurance exercises are components of a variety of muscle-building programs. Weight training, calisthenics, and specific isometric exercises can build both strength and endurance, increasing the power of the

musculoskeletal system, and generally improving the whole body. They may or may not have aerobic benefit.

Movement and ADLs include housecleaning, running after playful toddlers, climbing stairs instead of riding in elevators, and so on. Household activities can also contribute to an active lifestyle.

Effects of Exercise on Major Body Systems

The human body was designed for motion, and regular exercise is necessary for its healthy functioning. The effects of regular exercise on major body systems are explored in the following sections and outlined in Table 34-4. People differ in the benefits they receive from exercise based on the patient's age and overall health status. People who choose inactive lifestyles or who are forced into inactivity by illness or injury are at high risk for serious health problems (see Effects of Immobility on the Body section starting on page 1253).

Cardiovascular System

To meet the demand for oxygen created by the rhythmic contraction and relaxation of skeletal muscle groups, the supply of oxygenated blood to skeletal muscle needs to be increased. The cardiovascular system meets this challenge by increasing the heart rate, increasing the contractile strength of the myocardium, and increasing stroke volume (volume of blood ejected), thus increasing cardiac output. Arterial (systolic) blood pressure is increased, and blood is shunted from the nonexercising tissues to the heart and muscles. Exercise also improves venous return because the contracting muscles compress superficial veins and push blood back to the heart against gravity. Over time, regular exercise results in cardiovascular conditioning and produces the following benefits:

- Increased efficiency of the heart
- Decreased heart rate and blood pressure
- Increased blood flow to all body parts
- Improved venous return
- Increased circulating fibrinolysin (substance that breaks up small clots)

Respiratory System

The respiratory and cardiovascular systems work together to make increased oxygen available to the muscles. During exercise, the depth of respiration, respiratory rate, gas exchange at the alveolar level, and rate of carbon dioxide excretion are increased. Over time, regular exercise leads to improved pulmonary functioning. Improvements in pulmonary function include:

- Improved alveolar ventilation
- Decreased work of breathing
- Improved diaphragmatic excursion

Musculoskeletal System

The rhythmic contraction and relaxation of muscle groups during exercise result in increased muscle mass, tone, strength, and increased joint mobility. The more a person exercises, the more strength the person has to exercise or work in the future. Regular exercise produces the following benefits:

- Increased muscle efficiency (strength) and flexibility
- Increased coordination
- Reduced bone loss
- Increased efficiency of nerve impulse transmission

Regular exercise is also believed to slow the effects of aging. For example, exercise has been shown to help prevent osteoporosis (the process of bone demineralization) associated with aging (Fletcher et al., 2018).

Metabolic Processes

The metabolic rate increases during exercise so that sufficient glucose and fatty acids can be converted to provide the energy needed for increased muscle function. During strenuous exercise, the metabolic rate can increase to up to 20 times the person's normal rate. Increased body heat and waste products are also produced. With regular exercise, the efficiency of metabolism and body temperature regulation is increased. Other benefits of exercise on the metabolic processes include:

- Increased triglyceride breakdown
- Increased gastric motility
- Increased production of body heat

Gastrointestinal System

During exercise, blood is shunted away from the stomach and intestines to the exercising muscles. With regular exercise:

- Appetite is increased.
- Intestinal tone is increased, which improves digestion and elimination.
- Weight may be controlled.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Urinary System

Regular exercise increases blood circulation, including improved blood flow to the kidneys. This allows the kidneys to maintain the body's fluid balance and acid–base balance more efficiently and to excrete body wastes.

Skin

Increased circulation resulting from regular exercise nourishes the skin. Thus, regular exercise aids in promoting the overall general health of the skin.

Psychosocial Outlook

Some of the most important benefits of regular exercise are psychological. These benefits include:

- Increased energy, vitality, and general well-being
- Improved sleep
- Improved appearance (body image)
- Improved self-concept
- Increased positive health behavior

Risks Related to Exercise

A common reason many people give for not exercising is fear of experiencing personal harm. Personal harm can include cardiovascular events, muscle injuries, or falling. The nurse must be responsive to these fears with realistic knowledge of the risks associated with exercise and specific prevention strategies.

Precipitation of a Cardiac Event

Although the risk of exercise precipitating a major cardiac event in a healthy person is minimal, the risk is much higher for people with known or suspected cardiovascular (cardiac, peripheral vascular, or cerebrovascular disease), metabolic (type 1 and type 2 diabetes mellitus), or renal disease. Thus, the American College of Sports Medicine recommends physically inactive patients with known cardiovascular, metabolic, or renal disease and/or those with signs or symptoms suggestive of these diseases should seek medical clearance before starting an exercise program, regardless of the intensity of the exercise (Riebe et al., 2015).

Orthopedic Discomfort and Disability

Orthopedic problems caused by irritation of bones, tendons, ligaments, and sometimes muscles are the most common injuries associated with exercise. This irritation may result from added weight-bearing stress or from collision with the ground, an object, or another person.

Other Health Problems

Other types of health problems may be associated with different types of exercise, depending to a large extent on external factors (temperature on a given day, humidity, pollution index, safety of the neighborhood) as well as internal factors (age, history of previous injury, overuse, obesity, health history). Examples of other health problems related to exercise include heat exhaustion or heat stroke, exercise-induced asthma, and chest pain related to overexertion.

Effects of Immobility on the Body

Lack of exercise, inactivity, or immobility related to illness or injury place a person at high risk for serious health problems (Eanes, 2018). Immobility can affect the major body systems and has been linked to a predisposition to many chronic health problems (Johns Hopkins Medicine, n.d.). The effects of immobility on major body systems are explored in the following sections and outlined in Table 34-4 on page 1250. Like the benefits a person receives from exercise, complications resulting from immobility differ in their occurrence and severity based on the patient's age and overall health status.

Cardiovascular System

The primary and serious effects of immobility on the cardiovascular system include increased cardiac workload, orthostatic hypotension, and venous stasis, with resulting venous thrombosis. Immobility results in an increased workload for the heart. With immobility, the skeletal muscles that normally compress valves in the leg veins and help to pump the blood back to the right side of the heart do not adequately contract. There is less resistance offered by the blood vessels and blood pools in the veins, thus increasing the venous blood pressure and changing the distribution of blood in the immobile person. As a result, the heart rate, cardiac output, and stroke volume increase.

Immobility predisposes the patient to thrombi formation because of venous stasis, especially in the legs, where normal muscular activity helps move blood toward the central circulatory system. During periods of immobility, calcium leaves the bones and enters the blood, where it influences blood coagulation, leading to an increased risk of thrombus formation.

A person who is immobile is more susceptible to developing orthostatic hypotension. The normal neurovascular adjustments that occur to maintain systemic blood pressure with position changes are not used during periods of

inactivity and become inoperative. A drop in blood pressure may occur as a result of a lack of vasoconstriction when changing from a supine to an upright position. The person tends to feel weak and faint when this condition occurs. See Chapter 26 for additional discussion of orthostatic hypotension.

Respiratory System

The effects of immobility on the respiratory system are related to decreased ventilatory effort and increased respiratory secretions. Immobility causes a decrease in the depth and rate of respirations, in part because of a reduced need for oxygen by body cells. When areas of lung tissue are not used over time, atelectasis (incomplete expansion or collapse of lung tissue) may occur. Immobility results in a poor exchange of carbon dioxide and oxygen, upsets their balance in the body, and eventually causes an acid–base imbalance.

When a person is immobile, the movement of secretions in the respiratory tract is decreased, causing secretions to pool and leading to respiratory congestion. These conditions predispose the person to respiratory tract infections. Hypostatic pneumonia is a type of pneumonia that results from inactivity and immobility. The situation worsens when the person is dehydrated or using pharmacologic agents that increase the tenacity of secretions, depresses the coughing mechanism and/or depresses respirations.
